CONTENTS

Preface

Technical Committees and Task Groups

Contributors

THEORY

Chapter
1. **Thermodynamics and Refrigeration Cycles** (TC 1.1, Thermodynamics and Psychrometrics; TC 8.3, Absorption and Heat Operated Machines)
2. **Fluid Flow** (TC 1.3, Heat Transfer and Fluid Flow)
3. **Heat Transfer** (TC 1.3)
4. **Two-Phase Flow** (TC 1.3)
5. **Mass Transfer** (TC 1.3)
6. **Psychrometrics** (TC 1.1)
7. **Sound and Vibration** (TC 2.6, Sound and Vibration Control)

GENERAL ENGINEERING DATA

Chapter
8. **Physiological Principles and Thermal Comfort** (TC 2.1, Physiology and Human Environment)
9. **Environmental Control for Animals and Plants** (TC 2.2, Plant and Animal Environment; Committee SE-300 of the American Society of Agricultural Engineers)
10. **Physiological Factors in Drying and Storing Farm Crops** (TC 2.2)
11. **Air Contaminants** (TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment; TC 2.4, Particulate Air Contaminants and Particulate Contaminant Removal Equipment)
12. **Odors** (TC 2.3)
13. **Measurement and Instruments** (TC 1.2, Instruments and Measurements)
14. **Airflow Around Buildings** (TC 2.5, Air Flow Around Buildings)

BASIC MATERIALS

Chapter
15. **Combustion and Fuels** (TC 3.7, Fuels and Combustion)
16. **Refrigerants** (TC 3.1, Refrigerants and Brines)
17. **Refrigerant Properties** (TC 3.1)
18. **Secondary Coolants (Brines)** (TC 3.1)
19. **Sorbents and Desiccants** (TC 3.5, Desiccant and Sorption Technology)
20. **Thermal Insulation and Vapor Retarders—Fundamentals** (TC 4.4, Thermal Insulation and Moisture Retarders)
21. **Thermal Insulation and Vapor Retarders—Applications** (TC 4.4)
22. **Thermal and Water Vapor Transmission Data** (TC4.4)

LOAD AND ENERGY CALCULATIONS

Chapter
23. **Infiltration and Ventilation** (TC 4.3, Ventilation Requirements and Infiltration)
24. **Weather Data** (TC 4.2, Weather Information)
25. **Residential Cooling and Heating Load Calculations** (TC 4.1, Load Calculation Data and Procedures)
26. **Nonresidential Air-Conditioning Cooling and Heating Load** (TC 4.1)
27. **Fenestration** (TC 4.5, Fenestration)
28. **Energy Estimating Methods** (T.C. 4.7, Energy Calculations)
29. **Cooling and Freezing Times of Foods**
30. **Thermal Properties of Foods**

DUCT AND PIPE SIZING

Chapter
31. **Space Air Diffusion** (TC 5.3, Room Air Distribution)
32. **Duct Design** (TC 5.2, Duct Design)
33. **Pipe Sizing** (TC 6.1, Hydronic and Steam Equipment and Systems)

GENERAL

Chapter
34. **Abbreviations and Symbols** (TC 1.6, Terminology)
35. **Units and Conversions** (TC 1.6)
36. **Physical Properties of Materials** (TC 1.3)
37. **Environmental Health** (Environmental Health Committee)
38. **Codes and Standards**

ERRATA

INDEX

Composite index to the 1990 Refrigeration Systems and Applications, 1991 HVAC Applications, 1992 HVAC Systems and Equipment, 1993 Fundamentals, and the HVAC chapters in the 1988 Equipment volumes.

CONTRIBUTORS

In addition to the Technical Committees, the following individuals contributed significantly to this volume. The appropriate chapter numbers follow each contributor's name.

S.A. Sherif (2)
University of Florida

A.E. Bergles (3)

ASHRAE TECHNICAL COMMITTEES AND TASK GROUPS

SECTION 1.0—FUNDAMENTALS AND GENERAL
- 1.1 Thermodynamics and Psychrometrics
- 1.2 Instruments and Measurements
- 1.3 Heat Transfer and Fluid Flow
- 1.4 Control Theory and Application
- 1.5 Computer Applications
- 1.6 Terminology
- 1.7 Operation and Maintenance Management
- 1.8 Owning and Operating Costs
- 1.9 Electrical Systems
- 1.10 Energy Resources

SECTION 2.0—ENVIRONMENTAL QUALITY
- 2.1 Physiology and Human Environment
- 2.2 Plant and Animal Environment
- 2.3 Gaseous Air Contaminants and Gas Contaminant Removal Equipment
- 2.4 Particulate Air Contaminants and Particulate Contaminant Removal Equipment
- 2.5 Air Flow Around Buildings
- 2.6 Sound and Vibration Control
- TG Global Climate Change
- TG Halocarbon Emissions
- TG Safety
- TG Seismic Restraint Design

SECTION 3.0—MATERIALS AND PROCESSES
- 3.1 Refrigerants and Brines
- 3.2 Refrigerant System Chemistry
- 3.3 Contaminant Control in Refrigerating Systems
- 3.4 Lubrication
- 3.5 Desiccant and Sorption Technology
- 3.6 Corrosion and Water Treatment
- 3.7 Fuels and Combustion

SECTION 4.0—LOAD CALCULATIONS AND ENERGY REQUIREMENTS
- 4.1 Load Calculation Data and Procedures
- 4.2 Weather Information
- 4.3 Ventilation Requirements and Infiltration
- 4.4 Thermal Insulation and Moisture Retarders
- 4.5 Fenestration
- 4.6 Building Operation Dynamics
- 4.7 Energy Calculations
- 4.9 Building Envelope Systems
- 4.10 Indoor Environmental Modeling
- TG Cold Climate Design

SECTION 5.0—VENTILATION AND AIR DISTRIBUTION
- 5.1 Fans
- 5.2 Duct Design
- 5.3 Room Air Distribution
- 5.4 Industrial Process Air Cleaning (Air Pollution Control)
- 5.5 Air-to-Air Energy Recovery
- 5.6 Control of Fire and Smoke
- 5.7 Evaporative Cooling
- 5.8 Industrial Ventilation
- 5.9 Enclosed Vehicular Facilities
- TG Kitchen Ventilation

SECTION 6.0—HEATING EQUIPMENT, HEATING AND COOLING SYSTEMS AND APPLICATIONS
- 6.1 Hydronic and Steam Equipment and Systems
- 6.2 District Heating and Cooling
- 6.3 Central Forced Air Heating and Cooling Systems
- 6.4 In Space Convection Heating
- 6.5 Radiant Space Heating and Cooling
- 6.6 Service Water Heating
- 6.7 Solar Energy Utilization
- 6.8 Geothermal Energy Utilization
- 6.9 Thermal Storage

SECTION 7.0—PACKAGED AIR-CONDITIONING AND REFRIGERATION EQUIPMENT
- 7.1 Residential Refrigerators and Food Freezers
- 7.4 Unitary Combustion-Engine-Driven Heat Pumps
- 7.5 Room Air Conditioners and Dehumidifiers
- 7.6 Unitary Air Conditioners and Heat Pumps

SECTION 8.0—AIR-CONDITIONING AND REFRIGERATION SYSTEM COMPONENTS
- 8.1 Positive Displacement Compressors
- 8.2 Centrifugal Machines
- 8.3 Absorption and Heat Operated Machines
- 8.4 Air-to-Refrigerant Heat Transfer Equipment
- 8.5 Liquid-to-Refrigerant Heat Exchangers
- 8.6 Cooling Towers and Evaporative Condensers
- 8.7 Humidifying Equipment
- 8.8 Refrigerant System Controls and Accessories
- 8.10 Pumps and Hydronic Piping
- 8.11 Electric Motors—Open and Hermetic

SECTION 9.0—AIR-CONDITIONING SYSTEMS AND APPLICATIONS
- 9.1 Large Building Air-Conditioning Systems
- 9.2 Industrial Air Conditioning
- 9.3 Transportation Air Conditioning
- 9.4 Applied Heat Pump/Heat Recovery Systems
- 9.5 Cogeneration Systems
- 9.6 Systems Energy Utilization
- 9.7 Testing and Balancing
- 9.8 Large Building Air-Conditioning Applications
- 9.9 Building Commissioning
- 9.10 Laboratory Systems
- TG Clean Spaces
- TG Tall Buildings

SECTION 10.0—REFRIGERATION SYSTEMS
- 10.1 Custom Engineered Refrigeration Systems
- 10.2 Automatic Icemaking Plants and Skating Rinks
- 10.3 Refrigerant Piping, Controls, and Accessories
- 10.4 Ultra-Low Temperature Systems and Cryogenics
- 10.5 Refrigerated Distribution and Storage Facilities
- 10.6 Transport Refrigeration
- 10.7 Commercial Food and Beverage Cooling, Display and Storage
- 10.8 Refrigeration Load Calculations

SECTION 11.0—REFRIGERATED FOOD TECHNOLOGY AND PROCESSING
- 11.2 Foods and Beverages
- 11.5 Fruits, Vegetables and Other Products

PREFACE

While much of the information in the Fundamentals Handbook does not change, research supported by ASHRAE and other organizations continues to generate new information for many chapters. In this 1993 volume, several changes and additions are worth noting. One of the important additions is the new Chapter 37 on enviromental health, which introduces the field of environmental health as it pertains to buildings. Chapter 8 on physiological principles and thermal comfort has been revised to complement this new chapter. For example, Chapter 8 includes a revised comfort chart that accounts for the effect of high humidity on comfort. Chapter 27 on fenestration contains new data for a variety of fenestration products, including quadruple glazing, operable and fixed units, double doors, and sloped skylights.

Chapters 16 and 17 now have design data and pressure-enthalpy charts for six new refrigerants—R-32, R-123, R-124, R-125, R-134a, and R-141b. Also, Chapter 18 includes data on the physical and thermal properties of several new secondary coolants.

Chapter 10 on physiological factors in drying and storing farm crops and Chapter 19 on sorbents and desiccants were substantially rewritten for the 1989 volume, but minor changes and corrections are included in this volume. Chapter 26 on nonresidential air-conditioning cooling and heating loads was rewritten for 1989 and revised again in 1993. Residential cooling load information is incorporated into Chapter 25 on residential cooling and heating load calculations. Compared to its 1989 counterpart, Chapter 26 now more clearly differentiates and compares the transfer function (TFM), cooling load temperature difference/cooling load factor (CLTD/CLF), and the total equivalent temperature difference/time averaging (TETD/TA) methods for calculating air-conditioning loads.

Chapter 31 on space air diffusion now includes information on displacement ventilation, localized ventilation, and standards for satisfactory conditions of comfort. Chapter 32 on duct design reflects recent research that developed a database for duct fitting loss coefficients. This database, which is available from ASHRAE in an electronic format for personal computers, includes coefficients for over 200 fittings in a wide range of configurations. Finally, Chapter 38, which is updated every year, lists most of the current United States and Canadian standards that relate to the industry.

Additions and corrections for the 1991 and 1992 Handbooks precede the index. Errors found in this volume will be reported in the 1994 ASHRAE *Handbook—Refrigeration*. The Handbook Committee welcomes reader input. If you have suggestions or comments on improving a chapter, write to: Handbook Editor, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329.

Absorption Cycles in Practice 1.21
Characteristics of Refrigerant-Absorbent Pair 1.21
Thermodynamic Analysis 1.22
Water-Lithium Bromide Machine 1.22
Ammonia-Water Cycle 1.23

THERMODYNAMICS is the study of energy, its transformations, and its relation to states of matter. This chapter covers the application of thermodynamics to refrigeration cycles. The first part reviews the first and second laws of thermodynamics and presents methods for calculating thermodynamic properties. The second and third parts address compression and absorption refrigeration cycles, the two most common methods of thermal energy transfer.

THERMODYNAMICS

A *thermodynamic system* is a region in space or a quantity of matter bounded by a closed surface. The surroundings include everything external to the system, and the system is separated from the surroundings by the system boundaries. These boundaries can be movable or fixed, real or imaginary.

The concepts that operate in any thermodynamic system are *entropy* and *energy*. Entropy(s) measures the molecular disorder of a given system. The more shuffled a system, the greater its entropy; conversely, an orderly or unmixed configuration is one of low entropy.

Energy has the capacity for producing an effect, and can be categorized into either stored or transient forms. Stored forms of energy include the following:

Thermal (internal) energy u is the energy possessed by a system caused by the motion of the molecules and/or intermolecular forces.

Potential energy P.E. is the energy possessed by a system caused by the attractive forces existing between molecules, or the elevation of the system.

$$P.E. = mgz \tag{1}$$

where

m = mass
g = local acceleration of gravity
z = elevation above horizontal reference plane

Kinetic energy K.E. is the energy possessed by a system caused by the velocity of the molecules.

$$K.E. = mV^2/2 \tag{2}$$

where

m = mass
V = velocity of fluid streams crossing system boundaries

Chemical energy E_c is energy possessed by the system caused by the arrangement of atoms composing the molecules.

Nuclear (atomic) energy E_a is energy possessed by the system from the cohesive forces holding protons and neutrons together as the atom's nucleus.

Transient energy forms include the following:

Heat Q is the mechanism that transfers energy across the boundary of systems with differing temperatures, always in the direction of the lower temperature.

Work is the mechanism that transfers energy across the boundary of systems with differing pressures (or force of any kind), always in the direction of the lower pressure. If the total effect produced in the system can be reduced to the raising of a weight, then nothing but work has crossed the boundary.

Mechanical or *shaft work W* is the energy delivered or absorbed by a mechanism, such as a turbine, air compressor, or internal combustion engine.

Flow work is energy carried into or transmitted across the system boundary because a pumping process occurs somewhere outside the system, causing fluid to enter the system. It can be more easily understood as the work done by the fluid just outside the system on the adjacent fluid entering the system to force or push it into the system. Flow work also occurs as fluid leaves the system.

$$\text{Flow Work (per unit mass)} = pv \tag{3}$$

where p is the pressure and v is the specific volume, or the volume displaced per unit mass.

A *property* of a system is any observable characteristic of the system. The *state* of a system is defined by listing its properties. The most common thermodynamic properties are temperature T, pressure p, and specific volume v or density ρ. Additional

The preparation of the first and second parts of this chapter is assigned to TC 1.1, Thermodynamics and Psychrometrics. The third part is assigned to TC 8.3, Absorption and Heat Operated Machines.

thermodynamic properties include entropy, stored forms of energy, and enthalpy.

Frequently, thermodynamic properties combine to form new properties. *Enthalpy h*, a result of combining properties, is defined as:

$$h = u + pv \tag{4}$$

where

u = internal energy
p = pressure
v = specific volume

Each property in a given state has only one definite value, and any property always has the same value for a given state, regardless of how the substance arrived at that state.

A *process* is a change in state that can be defined as any change in the properties of a system. A process is described by specifying the initial and final equilibrium states, the path (if identifiable), and the interactions that take place across system boundaries during the process.

A *cycle* is a process or a series of processes wherein the initial and final states of the system are identical. Therefore, at the conclusion of a cycle, all the properties have the same value they had at the beginning.

A *pure substance* has a homogeneous and invariable chemical composition. It can exist in more than one phase, but the chemical composition is the same in all phases.

If a substance exists as liquid at the saturation temperature and pressure, it is called *saturated liquid.* If the temperature of the liquid is lower than the saturation temperature for the existing pressure, it is called either a *subcooled liquid* (the temperature is lower than the saturation temperature for the given pressure) or a *compressed liquid* (the pressure is greater than the saturation pressure for the given temperature).

When a substance exists as part liquid and part vapor at the saturation temperature, its quality is defined as the ratio of the mass of vapor to the total mass. Quality has meaning only when the substance is in a saturated state, *i.e.*, at saturation pressure and temperature.

If a substance exists as vapor at the saturation temperature, it is called *saturated vapor.* (Sometimes the term *dry saturated vapor* is used to emphasize that the quality is 100%.) When the vapor is at a temperature greater than the saturation temperature, it is *superheated vapor.* The pressure and temperature of superheated vapor are independent properties, since the temperature can increase while the pressure remains constant. Gases are highly superheated vapors. Figure 1 depicts these thermodynamic fluid states.

FIRST LAW OF THERMODYNAMICS

The first law of thermodynamics is often called the *law of the conservation of energy.* The following form of the first law equation is valid only in the absence of a nuclear or chemical reaction.

Based on the first law or the law of conservation of energy for any system, open or closed, there is an energy balance as:

$$\begin{bmatrix}\text{Net Amount of Energy}\\ \text{Added to System}\end{bmatrix} = \begin{bmatrix}\text{Net Increase in Stored}\\ \text{Energy of System}\end{bmatrix}$$

or

Energy In − Energy Out = Increase in Energy in System

Referring to Figure 2, Δm_1 is the mass entering the system, and Δm_2 is the mass leaving. The first law in differential or incremental form becomes:

$$[\Delta m(e + pv)]_{in} - [\Delta m(e + pv)]_{out} + \Delta Q - \Delta W = dE \tag{5}$$

$$\Delta m_1\left(u_1 + p_1v_1 + \frac{V_1^2}{2} + z_1g\right) - \Delta m_2 \times \left(u_2 + p_2v_2 + \frac{V_2^2}{2} + z_2g\right) + \Delta Q - \Delta W = dE \tag{6}$$

where ΔQ and ΔW are the increments of work and heat, and dE is the differential change in the energy of the system; if expressed as a rate equation:

$$\left(\frac{\Delta m_1}{\Delta t}\right)\left(h_1 + \frac{V_1^2}{2} + z_1g\right) - \left(\frac{\Delta m_2}{\Delta t}\right) \times \left(h_2 + \frac{V_2^2}{2} + z_2g\right) + \frac{\Delta Q}{\Delta t} - \frac{\Delta W}{\Delta t} = \frac{dE}{\Delta t} \tag{7}$$

as

$$\Delta t \to 0, \quad \frac{\Delta Q}{\Delta t} \to \dot{Q}, \quad \frac{\Delta W}{\Delta t} \to \dot{W},$$

$$\frac{\Delta m_1}{\Delta t} \to \dot{m}_1, \quad \frac{\Delta m_2}{\Delta t} \to \dot{m}_2, \quad \frac{dE}{\Delta t} \to \frac{dE}{dt}$$

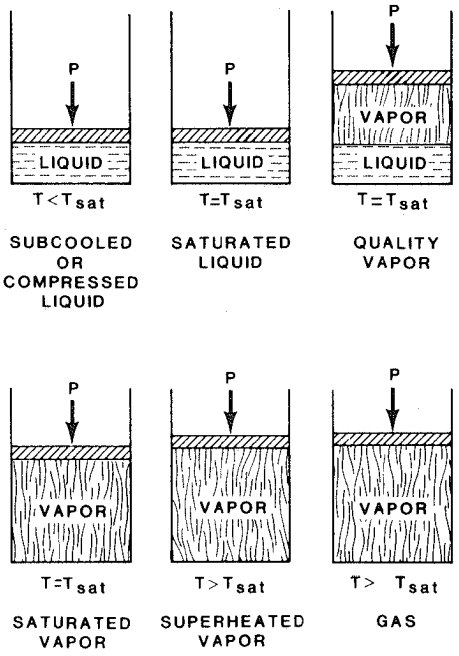

Fig. 1 Thermodynamic Fluid States

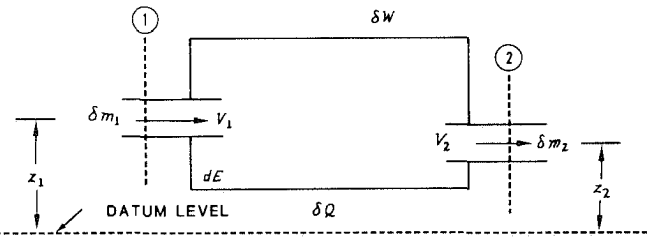

Fig. 2 Energy Flows in General Thermodynamic System

where

$\Delta Q/\Delta t = \dot{Q}$ = rate of heat transfer to system
$\Delta W/\Delta t = \dot{W}$ = rate at which work is performed by system, other than flow work pv
$\Delta m/\Delta t = \dot{m}$ = rate of mass flow crossing system boundary
$dE/\Delta t$ = rate of change of system energy
V = velocity of fluid streams crossing system boundary
g = local acceleration of gravity
z = elevation above horizontal reference plane
u = internal energy of fluid per unit mass
v = volume of fluid per unit mass

In the most general case that allows integration of the first law equation:

1. The properties of the fluids crossing the boundary remain constant at each point on the boundary.
2. The flow rate is constant at each section where mass crosses the boundary. (The flow rate cannot change as long as all properties, including velocity, remain constant at each point.)
3. All interactions with the surroundings occur at a steady rate.

This integration yields:

$$\sum m_{in}\left(u + pv + \frac{V^2}{2} + gz\right)_{in} - \sum m_{out}\left(u + pv + \frac{V^2}{2} + gz\right)_{out} + Q - W = \left[m_f\left(u + \frac{V^2}{2} + gz\right)_f - m_i\left(u + \frac{V^2}{2} + gz\right)_i\right]_{system} \quad (8)$$

The steady-flow process is important in engineering applications. Steady flow signifies that all quantities associated with the system do not vary with time. Consequently,

$$\sum_{\substack{\text{all streams}\\ \text{leaving}}} \dot{m}\left(h + \frac{V^2}{2} + gz\right) - \sum_{\substack{\text{all streams}\\ \text{entering}}} \dot{m}\left(h + \frac{V^2}{2} + gz\right) + \dot{Q} - \dot{W} = 0 \quad (9)$$

where $h = u + pv$.

A second common application is the closed stationary system for which the first law equation reduces to:

$$Q - W = [m(u_f - u_i)]_{system} \quad (10)$$

SECOND LAW OF THERMODYNAMICS

In an open system, the second law of thermodynamics can be written in terms of entropy as:

$$dS_{system} = \left(\frac{\Delta Q}{T}\right) + \Delta m_i s_i - \Delta m_e s_e + dS_{irr} \quad (11)$$

where

dS_{system} = total change within system in time dt during process
$\Delta m_i s_i$ = entropy increase caused by mass entering
$\Delta m_e s_e$ = entropy decrease caused by mass leaving
$(\Delta Q/T)$ = entropy change caused by reversible heat transfer between system and surroundings
dS_{irr} = entropy created caused by irreversibilities

Equation (11) accounts for all entropy changes in the system. Rearranging, this equation becomes:

$$\Delta Q = T\left[(\Delta m_e s_e - \Delta m_i s_i) + dS_{sys} - dS_{irr}\right] \quad (12)$$

In integrated form, if inlet and outlet properties, mass flow rates, and interactions with the surroundings do not vary with time, the general equation for the second law is:

$$(S_f - S_i)_{system} = \int_{rev} \frac{\Delta Q}{T} + \sum(ms)_{in} - \sum(ms)_{out} + \Delta S_{produced} \quad (13)$$

Available energy is energy in the form of shaft work or in a form completely convertible to shaft work by ideal processes. Energy that is in part convertible and in part nonconvertible is made up of an available part (the availability of energy) and an unavailable part (the unavailability of energy).

In thermodynamics, availability of energy is restricted to availability of energy for performing work (mechanical or electrical). The second law of thermodynamics limits transformation of heat into work, because only a portion of the heat available for heating can perform work. Therefore, the availability of energy is less than the quantity of heat under consideration.

Thermodynamic availability is useful for evaluating system performance and showing direction for improvement. The availability depends not only on system properties and interactions, but on conditions of the appropriate, naturally occurring thermal sink or source, denoted by the subscript o.

To determine availability, a reference condition that has no available energy must be specified. This reference condition is selected when the system is (1) at rest (zero velocity); (2) at the reference elevation (zero potential energy); (3) at the same pressure p_o and temperature T_o as the atmosphere; and (4) at chemical equilibrium (for reactive systems).

Irreversibility or *available energy degraded* is the decrease in the available energy due to irreversibilities and is equal to the reversible work minus the actual work for a process.

Reversible work refers to the maximum useful work obtained for a given change of state. It includes heat supplied from other systems, but excludes work done on the surroundings.

For the steady-flow system considered above, the availability formulation of the second law of thermodynamics is:

$$\dot{A}_Q + \dot{m}(a_f)_1 = \dot{m}(a_f)_2 + \dot{A}_W + \dot{I} \quad (14)$$

where

$\dot{A}_Q$ = rate of availability of heat transfer to system
$\dot{A}_W$ = rate of availability of work transfer from system
a_f = availability per unit flowing mass (flow availability)
$\dot{I}$ = irreversibility rate (always greater than zero)

Each of the terms $\dot{A}_Q, \dot{A}_W$, and a_f is evaluated by considering the maximum work achievable from the associated energy form, while $\dot{I}$ must be evaluated from Equation (14).

The availability of a heat transfer rate $\dot{Q}$ that occurs at temperature T is:

$$\dot{A}_Q = (1 - T_o/T)\,\dot{Q} \quad (15)$$

Often, $\dot{A}_Q$ is denoted by E_A and its converse, the unavailable energy, by E_U:

$$E_A = Q(1 - T_o/T) \quad \text{and} \quad E_U = Q - E_A = Q(T_o/T)$$

The availability of a steady work transfer rate $\dot{W}$ equals the work rate.

Flow availability a_f is the maximum work that can be obtained by allowing a unit mass of the flowing fluid to come into equilibrium with surroundings:

$$a_f = h + gZ + \frac{V^2}{2} - T_o s - \left(h_o + gZ_o + \frac{V_o^2}{2} - T_o s\right) \quad (16)$$

FIRST AND SECOND LAW ANALYSES OF REFRIGERATION CYCLES

Refrigeration cycles continually transfer thermal energy from a region of low temperature to one of higher temperature. The higher temperature heat sink is usually provided by ambient air or cooling water. This temperature, designated T_o, is the temperature of the surroundings.

The energy balance of the first law allows analysis and design of individual system components. The first law performance parameter for refrigeration systems is the coefficient of performance (COP), defined as:

$$\text{COP} = \frac{\text{Refrigerant Effect}}{\text{Net Work Input}} = \frac{|Q_2|}{|Q_1| - |Q_2|} \quad (17)$$

where $|Q_1|$ is the absolute value of heat transferred to the higher temperature sink, and $|Q_2|$ is the absolute value of heat transferred from the lower temperature source.

A second law analysis can demonstrate that (1) the reversed Carnot cycle is an ideal standard and the criterion for minimum requirement of work input to a compression refrigeration cycle; (2) departures from this ideal standard, such as fluid friction or heat transfer through a finite temperature difference, degrade available energy; and (3) such departures require that work input to the refrigeration cycle be greater than the ideal minimum. The increased work input equals the irreversibility evaluated from Equation (14). This represents total available energy, degraded by cyclic operation of the refrigerant and by heat transfer through finite temperature differences. An isolated system that includes the source, sink, and refrigeration unit performs as follows:

$$I = T_o(\Delta S_{sink} + \Delta S_{source}) = T_o(\Delta S_{total}) \quad (18)$$

EQUATIONS OF STATE

The equation of state of a pure substance is a mathematical relation between pressure, specific volume, and temperature, when the system is in thermodynamic equilibrium:

$$f(p,v,T) = 0 \quad (19)$$

The principles of statistical mechanics are used to (1) explore the fundamental properties of matter; (2) predict an equation of state based on the statistical nature of a particulate system; or (3) propose a functional form for an equation of state with unknown parameters that are determined by measuring thermodynamic properties of a substance. A fundamental equation with this basis is the *virial equation.*

The virial equation is expressed as an expansion in pressure p or in reciprocal values of volume per unit mass v:

$$\frac{pv}{RT} = 1 + B'p + C'p^2 + D'p^3 + \ldots \quad (20)$$

$$\frac{pv}{RT} = 1 + (B/v) + (C/v^2) + (D/v^3) + \ldots \quad (21)$$

where coefficients B', C', D', etc., and B, C, D, etc., are the virial coefficients. B' and B are second virial coefficients; C' and C are third virial coefficients, etc. The virial coefficients are functions of temperature only, and values of the respective coefficients in Equations (20) and (21) are related. For example, $B' = B/RT$ and $C' = (C - B^2)/(RT)^2$.

The quantity R is the ideal gas constant defined as:

$$R = \lim_{P \to 0} (pv)_T / T_{tp} \quad (22)$$

where $(pv)_T$ is the product of pressure and volume along an isotherm, and T_{tp} is the defined temperature of the triple point of water $T_{tp} = 491.69°\text{R}$. The current best value of R is 1545.32 $\text{ft} \cdot \text{lb}_f/\text{lb mole} \cdot °\text{R}$.

The quantity pv/RT is also referred to as the compressibility factor $Z = pv/RT$ or:

$$Z = 1 + (B/v) + (C/v^2) + (D/v^3) + \ldots \quad (23)$$

An advantage of the virial form is that statistical mechanics can be used to predict the lower order coefficients and provide physical significance to the virial coefficients. For example, in Equation (23), the term B/v is a function of interactions between two molecules, C/v^2 between three molecules, etc. Since the lower order interactions are common, the contributions of the higher order terms are successively less. Thermodynamicists use the partition or distribution function to determine virial coefficients; however, experimental values of the second and third coefficients are preferred. For dense fluid, many higher order terms are necessary that can neither be satisfactorily predicted from theory nor determined from experimental measurements. In general, a truncated virial expansion of four terms is valid for densities of less than one-half the value at the critical point. For higher densities, additional terms can be used and determined empirically.

Digital computers allow use of far more complex equations of state in calculating p-v-T values, even to high densities. The Benedict-Webb-Rubin (B-W-R) equation of state (Benedict *et al.* 1940) and the Martin-Hou equation (1955) have had considerable use, but should generally be limited to densities less than the critical value. Strobridge (1962) suggested a modified Benedict-Webb-Rubin relation that gives excellent results at higher densities and can be used for a p-v-T surface that extends into the liquid phase.

The B-W-R equation has been used extensively for hydrocarbons (Cooper and Goldfrank 1967). It is:

$$P = (RT/v) + (B_oRT - A_o - C_o/T^2)/v^2 + (bRT - a)/v^3 + a\alpha/v^6 + [c(1 + \gamma/v^2)e^{(-\gamma/v^2)}]/v^3T^2 \quad (24)$$

where the constant coefficients are A_o, B_o, C_o, a, b, c, α, γ.

The Martin-Hou equation, developed for fluorinated hydrocarbon properties, has been used to calculate the thermodynamic property tables in Chapter 17 and in ASHRAE *Thermodynamic Properties of Refrigerants* (Stewart *et al.* 1986). The Martin-Hou equation is as follows:

$$p = \frac{RT}{v-b} + \frac{A_2 + B_2T + C_2e^{(-kT/T_c^3)}}{(v-b)^2} + \frac{A_3 + B_3T + C_3e^{(-kT/T_c^3)}}{(v-b)^3} + \frac{A_4 + B_4T}{(v-b)^4} + \frac{A_5 + B_5T + C_5e^{(-kT/T_c^3)}}{(v-b)^5} + (A_6 + B_6T)e^{av} \quad (25)$$

where the constant coefficients are A_i, B_i, C_i, k, b, and α.

Strobridge (1962) suggested an equation of state that was developed for nitrogen properties and used for most cryogenic fluids. This equation combines the B-W-R equation of state with an equation for high density nitrogen suggested by Benedict (1937). These equations have been used successfully for liquid and vapor phases, extending in the liquid phase to the triple-point temperature and the freezing line, and in the vapor phase from 18 to 1800 °R, with pressures to 150,000 psi. The equation suggested by Strobridge is accurate within the uncertainty of the measured *p-v-T* data. This equation, as originally reported by Strobridge, is:

$$p = RT\rho + \left[Rn_1T + n_2 + \frac{n_3}{T} + \frac{n_4}{T^2} + \frac{n_5}{T^4}\right]\rho^2 + (Rn_6T + n_7)\rho^3 + n_8T\rho^4 + \rho^3\left[\frac{n_9}{T^2} + \frac{n_{10}}{T^3} + \frac{n_{11}}{T^4}\right]\exp(-n_{16}\rho^2) + \rho^5\left[\frac{n_{12}}{T^2} + \frac{n_{13}}{T^3} + \frac{n_{14}}{T^4}\right]\exp(-n_{16}\rho^2) + n_{15}\rho^6 \quad (26)$$

The 15 coefficients of this equation's linear terms are determined by a least-square fit to experimental data. Hust and Stewart (1966) and Hust and McCarty (1967) give further information on methods and techniques for determining equations of state.

In the absence of experimental data, Van der Waals' principle of corresponding states can predict fluid properties. This principle relates properties of similar substances by suitable reducing factors, *i.e.*, the *p-v-T* surfaces of similar fluids in a given region are assumed to be of similar shape. The critical point can be used to define reducing parameters to scale the surface of one fluid to the dimensions of another. Modifications of this principle, as suggested by Kamerlingh Onnes, a Dutch cryogenic researcher, have been used to improve correspondence at low pressures. The principle of corresponding states provides useful approximations, and numerous modifications have been reported. More complex treatments for predicting property values, which recognize similarity of fluid properties, are by generalized equations of state. These equations ordinarily allow for adjustment of the *p-v-T* surface by introduction of parameters. One example (Hirschfelder *et al.* 1958) allows for departures from the principle of corresponding states by adding two correlating parameters.

CALCULATING THERMODYNAMIC PROPERTY TABLES

The primary data used for these calculations are (1) *p-v-T* values over the entire range of application; (2) heat capacity values (c_p or c_v) along one isobar or isometric for the required temperature range; (3) vapor pressure values, where the application range includes phase changes; and (4) critical point and triple point data, where appropriate. Other measured values of thermodynamic properties can supplement these primary data or confirm the accuracy of the resulting property tables. These supplementary data include (1) heat capacities for additional isobars or isometrics, and of the saturated liquid; (2) Joule-Thomson data; and (3) velocity of sound measurements. This discussion is limited to calculating property tables from primary data.

Following are methods for calculation of thermodynamic property tables for the validity range of the equation of state. Many tables for the fluorinated hydrocarbons use Equation (25), which is not valid for the liquid phase. The following calculations limit application of Equation (25) to the gaseous phase. However, Equation (31) can be used for calculating saturated liquid properties, provided supplementary information is available for values of saturated volume v_f. The equations of state used for most cryogenic fluids are valid for gaseous and liquid phases; therefore, the following equations can be applied for both.

Calculating Entropy

Differences in entropy can be calculated along isotherms using *p-v-T* data and the Maxwell relations:

$$(\partial s/\partial p)_T = -(\partial v/\partial T)_p$$

or

$$\int_{s_1}^{s_2} ds = -\int_{p_1}^{p_2} (\partial v/\partial T)_p dp \quad (27)$$

and

$$(\partial s/\partial v)_T = (\partial p/\partial T)_v$$

or

$$\int_{s_1}^{s_2} ds = \int_{v_1}^{v_2} (\partial p/\partial T)_v dv \quad (28)$$

Differences in entropy can be calculated from heat capacity data. By definition,

$$c_p \equiv (\partial h/\partial T)_p \quad \text{and} \quad c_v \equiv (\partial u/\partial T)_v$$

However, $dh = Tds + vdp$, and at constant pressure $dp = 0$. Therefore:

$$c_p = T(\partial s/\partial T)_p \quad \text{and} \quad \int_{s_1}^{s_2} ds = \int_{T_1}^{T_2} (c_p/T)dT \quad (29)$$

Similarly, with:

$$c_v \equiv (\partial u/\partial T) \text{ and } du = Tds - pdv,\ c_v = T(\partial s/\partial T)_v \text{ and}$$

$$\int_{s_1}^{s_2} ds = \int_{T_1}^{T_2} (c_v/T)dT \quad (30)$$

Therefore, values of entropy along isobars or isometrics can be obtained from c_p or c_v data.

Changes in entropy during a phase change can be calculated from the vapor pressure data, and the *p-v-T* data at the phase boundaries using the Clapeyron equation:

$$(dp/dT) = (s_g - s_f)/(v_g - v_f) \quad (31)$$

where subscript g refers to the saturated vapor phase, subscript f refers to the saturated liquid phase, and dp/dT is the slope of the vapor pressure curve. This relation is valid for all first order changes.

The five relations given by Equations (27), (28), (29), (30), and (31) are functions for calculating an entropy table. Choice of function depends on the nature of the tabulation, *p-v-T* representation (equation of state), and availability of c_p or c_v data. The choice between $ds_{T=C} = -(\partial v/\partial T)_p dp$ or $ds_{T=C} = (\partial p/\partial T)_v dv$ is determined by the relative simplicity of the derivatives $(\partial v/\partial T)_p$ or $(\partial p/\partial T)_v$; the desire to calculate entropy values along isobars or isometrics; and the choice of either c_p or c_v data.

For example, if the heat capacity data to be used are c_p values along an isobar, then entropy differences are usually calculated along isotherms using the isobar for which c_p is known and the relation $ds_{T=C} = -(\partial v/\partial T)_p dp$ (see Figure 3).

Consider calculation of $S_2 - S_1$, where available information includes (1) an equation of state for the entire region of vapor and liquid of the form $p = p(T, v)$; (2) a vapor pressure function for values from the triple point to the critical point; and (3) c_p data along an isobar of standard pressure for this temperature range, represented by a function $c_p = c_p(T)$. The path for integration between 1 and 2 in Figure 3 is as noted. The entropy difference can be calculated as:

$$s_2 - s_1 = (s_a - s_1) + (s_b - s_a) + (s_c - s_b) + (s_d - s_c) + (s_2 - s_d) \quad (32)$$

$$s_2 - s_1 = \int_{T_1}^{p_a} -(\partial v/T)_p\, dp + \int_{p_a}^{T_b} (c_p/T)dT + \int_{T_2}^{p_c} -(\partial v/\partial T)_p\, dp + (dp/dT)(v_d - v_c) + \int_{T_2 p_d}^{p_2} -(\partial v/\partial T)_p (dp) \quad (33)$$

where the relation $(\partial v/\partial T)_p$ as a function of p along an isotherm is derived from the equation of state, and dp/dT is the slope of the vapor pressure curve at T_2. Specified states are identified by p and T, and heat capacity is known along an isobar. Although the equation of state is of form $p = p(T, v)$ and the derivative $(\partial p/\partial T)_v$ is simpler to determine, the relation is more simply expressed in terms of $(\partial v/\partial T)_p$.

Calculating Internal Energy and Enthalpy

To calculate internal energy and enthalpy, the techniques for calculating entropy are combined with the relations:

$$ds = (du/T) + (p/T)dv \quad (34)$$

$$ds = (dh/T) - (v/T)dp \quad (35)$$

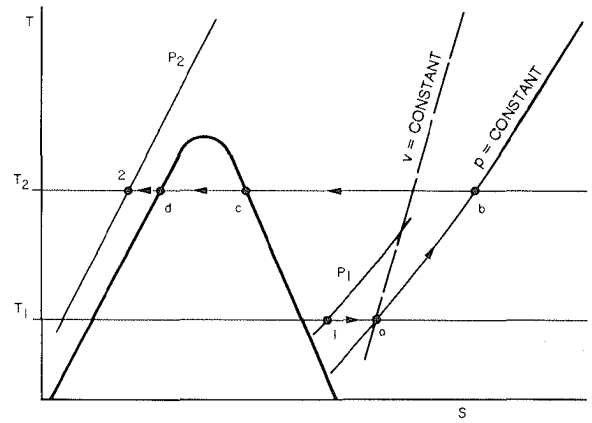

Fig. 3 Path of Integration for Entropy Calculation

These equations must be used with functions defining heat capacities $c_p \equiv (\partial h/\partial T)_p$ and $c_v \equiv (\partial u/\partial T)_v$, and the Clapeyron equation:

$$(dp/dT) = \frac{(h_g - h_f)}{T(v_g - v_f)}$$

For example, from Equation (34), $du = Tds - pdv$. Along an isotherm,

$$T\int_{s_1}^{s_2} ds$$

can be evaluated from Equation (27) or (28), with T = constant. The remaining problem for the isothermal variation of u is calculating

$$T\int_{v_1}^{v_2} pdv$$

along the isotherm. If the equation of state is of form $p = p(T,v)$, this calculation is usually simple. This suggests that the equation for internal energy changes along an isotherm that has limits of integration most consistent with the paths of the parameters of the problem is:

$$(u_2 - u_1)_{T=C} = T\int_{v_1}^{v_2} [T(\partial p/\partial T)_v - p]dv \quad (36)$$

Enthalpy can then be calculated from $h = u + pv$, *i.e.*:

$$(h_2 - h_1)_{T=C} = T\int_{v_1}^{v_2} [T(\partial p/\partial T)_v - p]dv + p_2 v_2 - p_1 v_1 \quad (37)$$

An alternate method for calculating internal energy and enthalpy differences along an isotherm is from Equation (35). Therefore, $dh = Tds + vdp$, and:

$$(h_2 - h_1)_{T=C} = T\int_{p_1}^{p_2} [-T(\partial v/\partial T)_p + v]dp \quad (38)$$

and

$$(u_2 - u_1)_{T=C} = T\int_{p_1}^{p_2} [-T(\partial v/\partial T)_P + v]dp - p_2 v_2 + p_1 v_1 \quad (39)$$

Equations (36) and (39) can be extended for internal energy and enthalpy changes along any combination of isothermal, isobaric, and isometric paths by combining with relations for the heat capacities. For example, from Equation (36), combining with the change in internal energy along a constant volume path:

$$du = c_v dT + [T(\partial p/\partial T)_v - p]dv \quad (40)$$

and from Equation (38), combining with the change of enthalpy along a constant pressure path:

$$dh = c_p dT + [v - T(\partial v/\partial T)_P]dp \quad (41)$$

Thermodynamic Property Calculations Based on *p-v-T* Relations and Zero-Pressure Specific Heats

Inaccurate heat data can cause significant errors in thermodynamic properties calculated as described previously. These errors are reduced by using zero-pressure specific heats calculated by methods of statistical mechanics from spectroscopic data, since ideal gas properties are more accurately known than real gas properties determined by calorimetric methods.

To use the zero-pressure specific heats, extend the isothermal path of integration to $p = 0$, as shown in Figure 3, *i.e.*, so that $a - b$ lies on the zero-pressure isobar. (The value of pv from the real gas equation of state must approach RT as p approaches zero.) Consequently, a reference state on the ideal gas surface is the most convenient choice. Since a reference point at zero pressure would result in infinite entropies at any finite pressure on the real or ideal gas surface, the standard reference state is usually chosen at 14.696 psi and T_o on the ideal gas surface. This is equivalent to choosing the standard reference values of enthalpy and internal energy at zeropressure and T_o, since h_o and u_o are functions of temperature alone for the ideal gas.

In the following discussion, superscript o denotes an ideal gas property, superscript * denotes a property (real or ideal) at zero pressure, and subscript o denotes a reference state property.

Figure 4 illustrates the path of integration for the following derivation. Paths $o - a$ and $b - c$ are defined by Equations (28) and (37). Path $a - b$ is defined by Equation (29) and the following relation:

$$\int_{h_1}^{h_2} dh = \int_{T_1}^{T_2} c_p dT$$

Equations (42) and (43) are the result of these integration paths.

$$s_c = s_{T_o^o} + \int_{T_o}^{v_a^*} (\partial p/\partial T)_v dv + \int_{v_b^*}^{v_c} (\partial p/\partial T)_v dv + \int_{T_o}^{T_c} (c_p^*/T) dT \tag{42}$$

$$h_c = h_{T_o^o} + \int_{v_o^*}^{v_a} [T(\partial P/\partial T)_v - p] dv + \int_{v_b^*}^{v_c} [T(\partial p/\partial T)_v - p] dv + \int_{T_o}^{T_c} c_p^o dT + p^* v_a^* - p_o v_o + p_c v_c - p^* v_b^* \tag{43}$$

The limit must be introduced as p^* approaches zero, since only then do the real and ideal gas surfaces coincide. For the ideal gas, $(\partial p/\partial T)_v$ is independent of temperature $[(\partial p/\partial T)_v = R/v]$, and the first integral in Equation (42) can be evaluated at any temperature T:

$$\int_{v_o}^{v_a^*} (\partial p/\partial T)_v dv = \int_{v_o}^{v_a^*} (\partial p/\partial T)_v dv$$

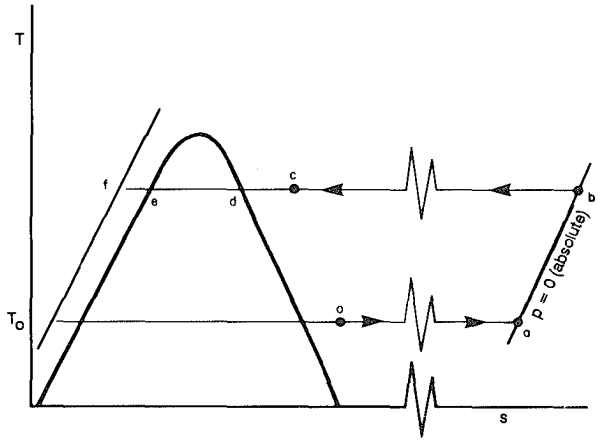

Fig. 4 Path of Integration for Property Calculation

This integral is then replaced by three integrals:

$$\int_{v_o}^{v_a^*} (\partial p/\partial T)_v dv = \int_{v_o}^{v_c^*} (\partial p/\partial T)_v dv + \int_{v_c}^{v_b^*} (\partial p/\partial T)_v dv + \int_{v_b^*}^{v_a^*} (\partial p/\partial T)_v dv$$

and is finally evaluated, using $v_b^* = RT_c/p^*$ and $v_a^* = RT_o/p^*$, to obtain:

$$\int_{v_o}^{v_a^*} (\partial p/\partial T)_v dv = R\left(\ln \frac{v_c T_o}{v_o T_c}\right) - \int_{v_b^*}^{v_c} (R/v) dv$$

Substitution into Equation (42) yields in the limit:

$$s = s_{T_o^o} + R\left(\ln \frac{p_o v_c}{RT_c}\right) + \int_{v_c}^{\infty} [(R/v) - (\partial p/\partial T)_v] dv + \int_{T_o}^{T_c} (c_p^o/T) dT \tag{44}$$

A similar simplification of Equation (43) yields:

$$h_c = (h_{T_o})^0 + \int_{v_c}^{\infty} [p - T(\partial p/\partial T)_v] dv + (p_c v_c - RT_c) + \int_{T_o}^{T_c} c_p^o dT \tag{45}$$

Equations (46) and (47) are obtained by substituting $v = 1/\rho$ and $dv = -(d\rho/\rho^2)$ into Equations (44) and (45), respectively:

$$s = (s_{T_o})^0 - R\left(\ln \frac{\rho_c RT_c}{p_o}\right) + \int_{\rho=0}^{\rho_c} [(R/\rho) - (1/\rho^2)(\partial p/\partial T)_\rho] d\rho + \int_{T_o}^{T_c} (c_p^o/T) dT \tag{46}$$

$$h = (h_{T_o})^0 + \int_{\rho=0}^{\rho_c} [(p/\rho^2) - (T/\rho^2)(\partial p/\partial T)\rho] d\rho + (p_c - \rho_c RT)/\rho_c + \int_{T_o}^{T_c} c_p^o dT \tag{47}$$

The low-pressure (large volume) behavior of the real gas equation of state must be such that $pv \to RT$, *i.e.*, $(\partial P/\partial T)_v$ for the real gas must approach R/v to cancel the existing R/v term in Equation (44). If this is not the case, the remaining R/v term will integrate to $\ln(v)$, which is infinite at the upper limit.

Derivations similar to those above can be obtained from equations in which p and T are independent variables:

$$s = (s_{T_o})^0 + R\left(\ln \frac{p_o}{p}\right) + \int_{p=0}^{p} [(R/p) - (\partial v/\partial T)_p] dp + \int_{T_o}^{T} (c_p^o/T) dT \tag{48}$$

$$h = (h_{T_o})^0 + \int_{p=0}^{p} [v - T(\partial v/\partial T)_p] dp + \int_{T_o}^{T} c_p^o dT \tag{49}$$

COMPRESSION REFRIGERATION CYCLES

Thermodynamic analysis can generally be applied to any vapor compression system. This section gives examples of thermo-

dynamic analyses for the basic vapor compression system and for a two-stage vapor compression system with subcooling and intercooling. Thermodynamic considerations for a two-stage vapor compressor are introduced.

The discussion emphasizes second law analysis of the cycles, using the concepts introduced in the preceding section. Although pressure-enthalpy (p-h) coordinates are used most often to illustrate refrigeration cycles, temperature-entropy (T-S) coordinates better express second law concepts and are used in the following examples. Tripp (1966) and Tripp and Sun (1965) give additional examples of T-S coordinates for examining refrigeration cycles and compressors. Tripp and Sun (1965) introduce pressure-volume coordinates for thermodynamic analysis.

IDEAL BASIC VAPOR COMPRESSION REFRIGERATION CYCLE

Figure 5 illustrates the equipment diagram for the basic vapor compression cycle. Figures 6 and 7 show the p-h and T-S diagrams. Minimum components of this cycle include compressor, condenser, expansion valve, and evaporator. The ideal cycle considers heat transfer in the condenser and evaporator without pressure losses, a reversible adiabatic (isentropic) compressor, and an adiabatic expansion valve, connected by piping that has neither pressure loss nor heat transfer with the surroundings. The refrigerant leaves the evaporator at point 1 as a low-pressure, low-temperature, saturated vapor and enters the compressor, where it is compressed reversibly and adiabatically (isentropic). At point 2, it leaves the compressor as a high-temperature, high-pressure, superheated vapor and enters the condenser, where it is first desuperheated and then condensed at constant pressure. At point 3, the refrigerant leaves the condenser as a high-pressure, medium-temperature, saturated liquid and enters the expansion valve, where it expands irreversibly and adiabatically (constant enthalpy). At point 4, it leaves the expansion valve as a low-pressure, low-temperature, low quality vapor and enters the evaporator, where it is evaporated reversibly at constant pressure to the saturated state at point 1. Heat transfer to the evaporator and from the condenser occurs without a finite temperature difference between the fluid emitting the heat and the fluid that absorbs the heat, except during the desuperheating process in the condenser.

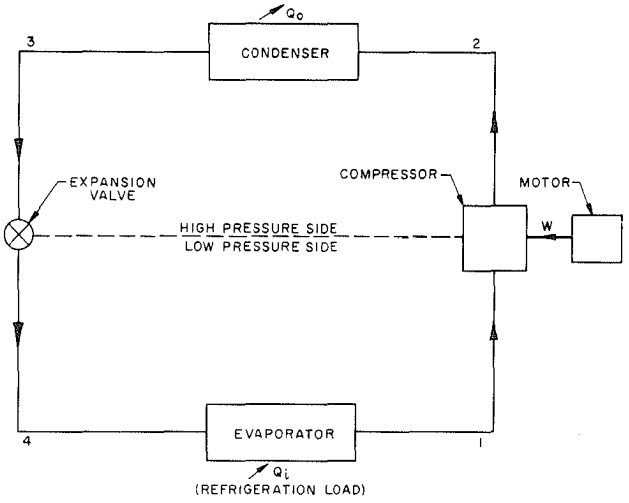

Fig. 5 Equipment Diagram for Basic Vapor Compression Cycle

Energy Balance and First Law Analysis

An energy balance and certain performance parameters can be derived from the first law of thermodynamics. Applying the steady-flow equation for the first law [Equation (9)] to each of the components of the basic vapor compression cycle, the following relationships are derived:

$$\text{1-2 Compression} \qquad {}_1\dot{W}_2 = -(h_2 - h_1)\dot{m} \qquad (50)$$

(This quantity is negative, indicating work is done by the compressor on the refrigerant.)

$$\text{2-3 Condensing} \qquad {}_2\dot{Q}_3 = -(h_2 - h_3)\dot{m} \qquad (51)$$

$$\text{3-4 Expansion valve} \qquad h_3 = h_4$$

$$\text{4-1 Evaporator} \qquad {}_4\dot{Q}_1 = (h_1 - h_4)\dot{m} \qquad (52)$$

In applying the steady-flow equation, kinetic energy and potential energy terms were omitted; because flow velocities are low to avoid fluid friction and undesirable pressure losses, and height variation within a given refrigeration system is usually small, these terms are numerically insignificant. Since the system is cyclic, the

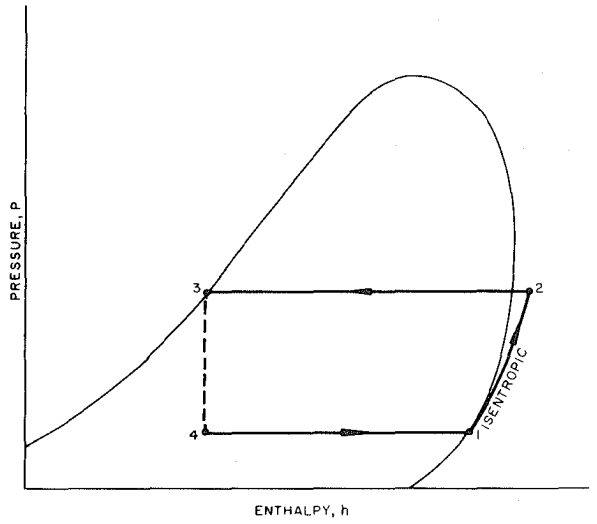

Fig. 6 Pressure-Enthalpy Diagram for Basic Vapor Compression Cycle

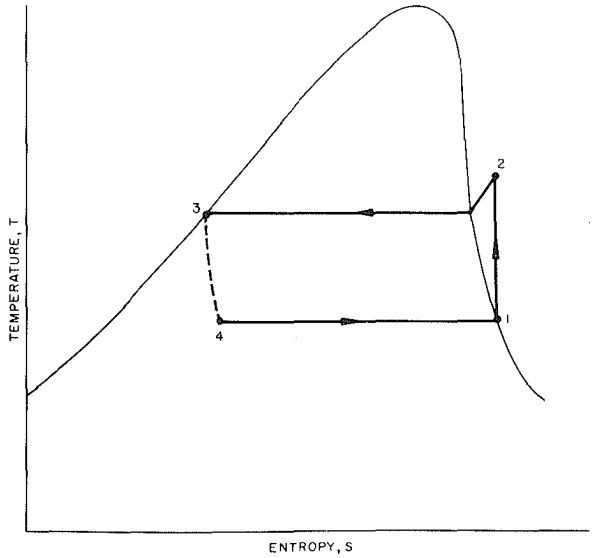

Fig. 7 Temperature-Entropy Diagram for Basic Vapor Compression Cycle

heat rejected in the condenser must equal the sum of the heat absorbed in the evaporator and the work of compression.

Coefficient of performance (COP) indicates the performance of a refrigeration system. The COP was introduced as Equation (17), *i.e.*, COP = refrigeration effect/net work input.

For the basic vapor compression cycle, from Equations (50) and (52), the COP is:

$$\text{COP} = (h_1 - h_4)/(h_2 - h_1)$$

Thermodynamic Analysis of the Compressor

The change in state between the inlet and outlet is (1) reversible and adiabatic (isentropic) for the ideal compressor, or (2) adiabatic and irreversible (with an increase in entropy in the fluid passing through the compressor). The variation from the ideal compressor is then described by the adiabatic compressor efficiency.

The effect of the clearance volume, *i.e.*, the volume the refrigerant occupies within the compressor that is not displaced by the moving member, is an important thermodynamic consideration for the positive displacement compressor. For the piston compressor, the gas in clearance volume between piston and cylinder head when the piston is in a top, center position reexpands to a larger volume as the cylinder discharges and the pressure falls to the inlet pressure (see Figure 8). Consequently, the compressor discharges a refrigerant mass less than the mass that would occupy the volume swept by the piston, measured at the inlet pressure and temperature. This effect is quantitatively expressed by the volumetric efficiency η_v:

$$\eta_v = m_a/m_t \tag{53}$$

where

m_a = actual mass of new gas entering compressor per stroke
m_t = theoretical mass of gas represented by displacement volume and determined at pressure and temperature at compressor inlet

For the basic vapor compression cycle, volumetric efficiency becomes:

$$\eta_v = \frac{V_a - V_d}{V_a - V_c} = 1 + C - C\frac{v_1}{v_2} \tag{54}$$

where

$C = V_c/(V_a - V_c)$ = clearance ratio
v_1 = specific volume of refrigerant at beginning of compression
v_2 = specific volume at end of compression

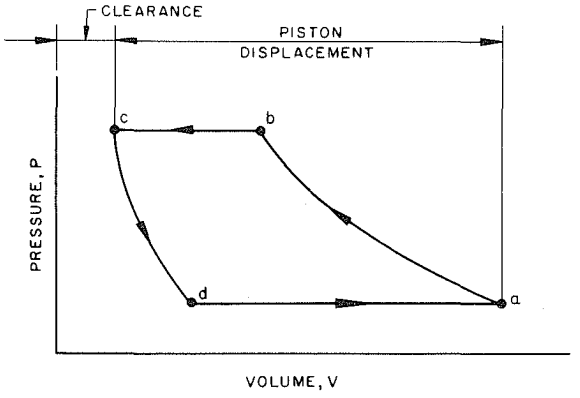

Fig. 8 Machine Cycle for Idealized Piston Compressor

Table 1 Effect of Interstage Pressure

Interstage Pressure, psia	Work Done per Unit of Cooling, Btu/min·ton		
	L.P. Compressor	H.P. Compressor	Total
18	0.0	79.0	79.0
28	15.0	61.6	76.6
38	25.7	49.3	75.0
48	34.1	39.7	73.8
58	41.0	31.8	72.8
68	46.9	25.1	72.0
78	52.1	19.2	71.3
88	56.6	14.0	70.6
98	60.7	9.4	70.1
115	66.8	2.4	69.2

Volumetric efficiency measures the effectiveness of the compressor's piston displacement (size) in moving the refrigerant vapor through the cycle. Since refrigerants differ in their specific volumes v_1, choice of refrigerant can affect the mass flow delivered by compressor displacement.

One of the design parameters of a multistage compressor is selection of the interstage pressure at which the refrigerant temperature is reduced by an intercooler. At optimum interstage pressure, total work is minimum. For two-stage compression of an ideal gas ($pv = RT$), this occurs at the geometric mean of the suction and discharge pressures and results in equal work for the stages. The application of multistage compressors to refrigeration systems, however, differs from gas compressors, since the interstage pressure is usually cooled by refrigerant diverted from some other part of the cycle. Table 1 lists the results of an analysis for a two-stage R-12 cycle (Qvale 1971a). The refrigerant at the low-pressure compressor inlet is at −3 °F and 18 psia, and the high-pressure discharge is at 117.90 °F and 120 psia. Adiabatic efficiency of the compressor is assumed to be 80%, pressure loss in the desuperheater is 1.5 psia, and the refrigerant leaves the desuperheater at 5 °F of superheat. (Also see Figure 19 and Tables 2 and 4.)

In most refrigeration multistage cycles, minimum work is obtained at an interstage pressure other than the geometric mean pressure. In the case considered in Table 1, however, the condition of minimum work is not a valid criterion for selecting the interstage pressure. In such cases, the geometric mean pressure is suggested for the interstage pressure as it yields approximately equal volumetric efficiencies for the two stages. Therefore, it is important to evaluate each specific cycle.

Other thermodynamic studies of compressor performance are detailed by Qvale (1971b) and Haseltine and Qvale (1971).

SECOND LAW THERMODYNAMIC ANALYSIS

In analyzing compression refrigeration cycles, the concepts of the reversible process and available energy are basic to the application of the second law of thermodynamics. From these basic concepts, the performance of a process or system can be expressed in terms of degradation (or loss) of available energy (irreversibility). The following examples (Tripp 1966) apply these concepts to compression refrigeration systems, relate the principles of irreversibility $I = T_o\Delta S_{total}$ and the degradation of available energy $(\Sigma E_A)_d$, and emphasize use of the *T-S* coordinates to illustrate the effects of losses in the refrigeration system.

REVERSED CARNOT CYCLE

For given temperatures of the refrigerated space and the atmosphere (usually ambient air or economically available water), a thermodynamically reversible cycle, such as the reversed Carnot cycle, has the highest possible coefficient of performance.

As shown on the *T-S* diagram of Figure 9, this cycle has four reversible processes: (1) isothermal expansion, from state 4 to state 1, during which heat (the refrigeration load) flows from refrigerated space to refrigerant; (2) adiabatic compression, from 1–2; (3) isothermal compression, from 2–3, in which heat flows from refrigerant to atmosphere; and (4) adiabatic expansion, from 3–4. Area (b) represents refrigeration load; area (a), net work input to the cycle; and area (a + b), heat rejection to the atmosphere. The ratio of areas (b/a) represents COP. Area (a + b) also represents unavailable heat flow both to and from the cycle, while the negative of area (a) represents the available portion of refrigeration load.

In Figure 9, the COP of the reversed Carnot cycle is a function of the absolute temperatures of refrigerated space T_R and atmosphere T_o.

$$\begin{aligned}\text{COP} &= \text{Refrigeration Load/Net Work Input}\\ &= Q_i/(Q_o - Q_i) = Q_i/W = T_R\,\Delta S/(T_o\Delta S - T_R\Delta S)\\ &= 1/[(T_o/T_R) - 1] \qquad (55)\end{aligned}$$

In this cycle, departures from ideal negligible temperature differences during heat transfer and reversible processes require a greater work input to the refrigeration cycle than the ideal minimum. Such departures degrade available energy and increase entropy of the system and its surroundings ΔS_{total}. Increased net work input equals the sum of all available energies degraded and also equals the product of absolute temperature of the atmosphere and increase in entropy $T_o\Delta S_{total}$. Ideal conditions are illustrated in Example 1, and departures from this ideal are shown in Examples 2 and 3.

Example 1. Determine entropy change, work, and coefficient of performance for the cycle shown in Figure 9. Temperature of the refrigerated space T_R is 400°R and that of the atmosphere T_o is 500°R. Refrigeration load is 200 Btu.

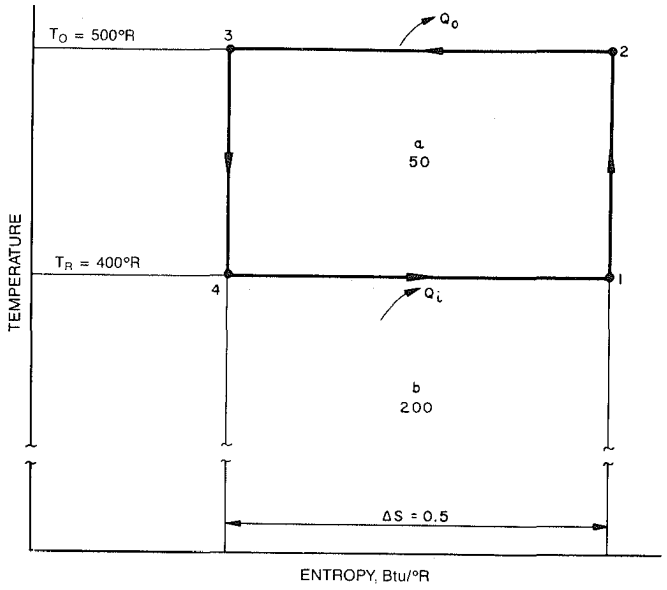

Fig. 9 Temperature-Entropy Diagram for Ideal Reversed Carnot Cycle of Example 1

Solution:

$$\Delta S = S_1 - S_4 = Q_i/T_R = 200/400 = 0.500 \text{ Btu/°R}$$
$$W = \Delta S(T_o - T_R) = 0.5\,(500 - 400) = 50 \text{ Btu}$$
$$\text{COP} = Q_i/(Q_o - Q_i) = Q_i/W = 200/50 = 4$$

Flow of energy, available energy E_A, unavailable energy E_U, and their area representations in Figure 9 are:

Energy	Btu	Area
Q_i	200	b
Q_o	250	a + b
W	50	a
$(E_A)_i$	− 50	− a
$(E_U)_i$	250	a + b
$(E_A)_o$	0	—
$(E_U)_o$	250	a + b

In Example 1, the entropy change of the isolated system as a result of the refrigeration cycle is zero. The net change of entropy of any refrigerant in any cycle is always zero. The change in entropy of the refrigerated space in Example 1 is $\Delta S_R = 200/400 = 0.5$ Btu/°R, and that of the atmosphere is $\Delta S_o = -250/500 = -0.5$ Btu/°R, giving a change in entropy of the isolated system of $\Delta S_{total} = \Delta S_R + \Delta S_o = 0$.

In Example 1, there is no degradation of available energy, as all processes in the cycle are assumed reversible and all heat flows occur with negligible temperature difference.

In actual cycles, heat transfer occurs with finite temperature differences, and all processes of the refrigerant involve friction. These processes are irreversible and cause degradation of available energy, an increase in entropy of the isolated system and an augmented work input to the cycle.

These concepts are expressed as:

$$\Delta W = W - W_{id} \qquad (56)$$

$$W = Q_o - Q_i \qquad (57)$$

$$W_{id} = (T_o - T_R)(-\Delta S_R) \qquad (58)$$

$$Q_o = T_o\Delta S_o \qquad (59)$$

$$Q_i = T_R(-\Delta S_R) \qquad (60)$$

Therefore:

$$\begin{aligned}\Delta W &= T_o\Delta S_o - T_R(-\Delta S_R) - (T_o - T_R)(-\Delta S_R)\\ &= T_o(\Delta S_o + \Delta S_R) = T_o\Delta S_{total} \qquad (61)\end{aligned}$$

Also:

$$Q_o = (E_A)_o + (E_U)_o \qquad (62)$$

$$(E_U)_o = (E_U)_R + (\Sigma E_{Ad})_r + (E_{Ad})_i \qquad (63)$$

$$(E_U)_R = T_o(-\Delta S_R) \qquad (64)$$

Therefore:

$$\begin{aligned}W &= (E_A)_o + T_o(-\Delta S_R) + (\Sigma E_{Ad})_r + (E_{Ad})_i\\ &\quad - T_R\,(-\Delta S_R) - (T_o - T_r)(-\Delta S_R)\\ &= (E_A)_o + (\Sigma E_{Ad})_r + (E_{Ad})_i = \Sigma E_{Ad} \qquad (65)\end{aligned}$$

where

$(E_U)_R$ = unavailable portion of energy removed from refrigerated space at temperature T_R

$(\Sigma E_{Ad})_r$ = sum of all available energy degraded by refrigerant in cyclical operation (see Examples 2 and 3)

$(E_A)_o$ = available energy outflow from refrigerant during process of heat rejection; $(E_A)_o$ is rendered unavailable when absorbed by atmosphere (see Example 3)

$(E_{Ad})_i$ = available energy degraded by heat transfer from refrigerated space to refrigerant when process is accomplished through finite temperature difference (see Example 3)

ACTUAL BASIC VAPOR COMPRESSION REFRIGERATION CYCLE

Although the basic vapor compression refrigeration cycle shown in Figures 6 and 7 has been called ideal, the cycle, in interaction with the atmosphere, entails two irreversibilities: (1) the inherent irreversibility in the expansion valve process and (2) the process of heat transfer through a finite temperature difference during the desuperheating of the vapor in the condenser. To remove the first irreversibility, a reversible adiabatic expansion engine should be substituted for the expansion valve, and work output from this engine would supply part of the work input to the cycle. The process for this engine is shown as process 3 to 4′ in Figure 10. To remove the second irreversibility, the compression process 1 to 2 of Figure 10 should be replaced by a reversible two-part compression, the isentropic process 1 to 2′ and the isothermal process 2′ to 2″ of Figure 10. These improvements produce a reversed Carnot cycle equal to the one in Figure 9, except that, due to increased entropy change during heat influx to the refrigerant, the refrigeration load, net work input, and heat rejection would all be increased by 4.52%.

The complexity of the equipment needed for these improvements precludes its application, and a feasible arrangement is shown in Figure 5.

In the following demonstrations, Example 2 presents a second law analysis of an ideal vapor cycle, as depicted in Figure 7, and Example 3 analyzes a vapor cycle that represents actual irreversible conditions of friction and heat transfer found in practice.

Example 2. The data are those of Example 1. The refrigerant is R-12. All processes are reversible, except those through the expansion valve. Heat transfer is accomplished with negligible temperature differences, except for the desuperheating process in the condenser. Figure 10 shows the cycle.

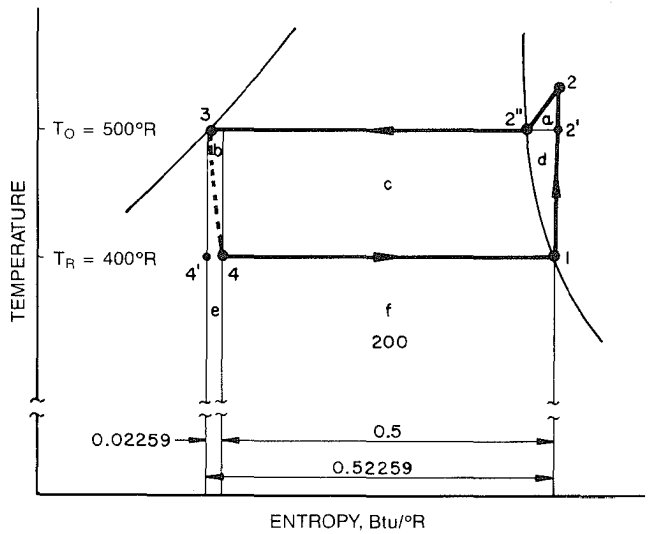

Fig. 10 Temperature-Entropy Diagram for Ideal Basic Vapor Cycle of Example 2

State-Point Properties

State	p, psia	t, °F	h, Btu/lb	s, Btu/lb·°R
1	5.409	−59.69	70.727	0.17708
2	51.94	77.31	87.295	0.17708
3	51.94	40.31	17.342	0.03759
4	5.409	−59.69	17.342	0.04362

$M = 200/(70.727 - 17.342) = 3.7465$ lb

$Q_o = 3.7465\,(87.295 - 17.342) = 262.07$ Btu

$W = 262.07 - 200 = 62.07$ Btu

COP $= 200/62.07 = 3.222$

$\Delta W = 62.07 - 50 = 12.07$ Btu

$\Delta S_R = -200/400 = -0.5$ Btu/°R

$\Delta S_o = 262.07/500 = 0.5241$ Btu/°R

$\Delta S_{total} = 0.5241 - 0.5 = 0.0241$ Btu/°R

$T_o\Delta S_{total} = 500\,(0.0241) = 12.07$ Btu

$(E_U)_o = 500\,(0.52259) = 261.29$ Btu

$(E_A)_o = 262.07 - 261.29 = 0.78$ Btu

$(E_{Ad})_r = 500\,(0.02259) = 11.29$ Btu

$\Sigma E_{Ad} = 11.29 + 0.78 = 12.07$ Btu

Energy	Btu	Area
Q_i	200	f
Q_o	262.07	(a→f)
W	62.07	(a→e)
$(E_A)_i$	−50	−(c+d)
$(E_U)_i$	250	c+d+f
$(E_A)_o$	0.78	a
$(E_U)_o$	261.29	(b→f)
$(E_{Ad})_r$	11.29	b+e

Example 3. In this case, deviations from the ideal vapor cycle of Example 2 are a combination of heat transfer through finite temperature differences, irreversible adiabatic compression, and pressure losses in the evaporator and condenser. The cooling is 200 Btu, and temperatures of the refrigerated space and the atmosphere are 400 and 500°R, respectively. The cycle is shown in Figure 11, in which the constant pressure process from state 2 to 3, is the equivalent reversible process of heat emission from the vapor as it is desuperheated and condensed. Figure 12 shows an enlargement of part of Figure 11.

State-Point Properties

State	p, psia	t, °F	h, Btu/lb	s, Btu/lb·°R
1	4.0053	−69.59	69.625	0.17907
1′	3.0	−69.59	69.615	0.18373
2	64.0	150	98.427	0.19328

$$Q_i + W = Q_o$$
$$200 + 115.14 = 315.14$$
$$Q_i = (E_A)_i + (E_U)_i$$
$$200 = -56.41 + 256.41$$
$$Q_o = (E_A)_o + (E_U)_o$$
$$315.14 = 12.64 + 302.50$$
$$W + (E_A)_i = (E_A)_o + (E_{Ad})_r$$
$$115.14 - 56.41 = 12.64 + 46.09$$
$$58.73 = 58.73$$
$$(E_U)_i + (E_{Ad})r = (E_U)_o$$
$$256.41 + 46.09 = 302.50$$

COMPLEX VAPOR COMPRESSION REFRIGERATION CYCLES

In large refrigeration systems, more equipment than needed for the basic vapor cycle shown in Figure 5 is sometimes advantageous. The design for a system can include many compressors, evaporators, expansion valves, and flash chambers. However, an optimum operational and economical system is the objective of any design.

A more complex design shown in Figure 13 includes two evaporators, two compressors, two expansion valves, and a single condenser. Evaporator II could have a higher vapor temperature (35 °F for the storage of fruits and vegetables) than Evaporator I (5 °F for frozen fish or poultry). Each evaporator could also carry a different load.

In the next example, second law analysis shows how introducing a flash chamber and doubling other equipment improves thermodynamic performance.

Example 4. In this cycle (see Figure 14), the data are those of Example 2. The equipment provides compound compression in a low-stage compressor (I) and a high-stage compressor (II), a flash intercooler, and two expansion valves. All processes of the refrigerant are reversible, except those in the flash intercooler and expansion valves.

When compared with the ideal basic vapor cycle of Example 2, the cycle in this example reduces (1) the irreversibilities caused by the refrigerant, (2) the available portion of heat rejected to the atmosphere, and (3) net work input to the cycle.

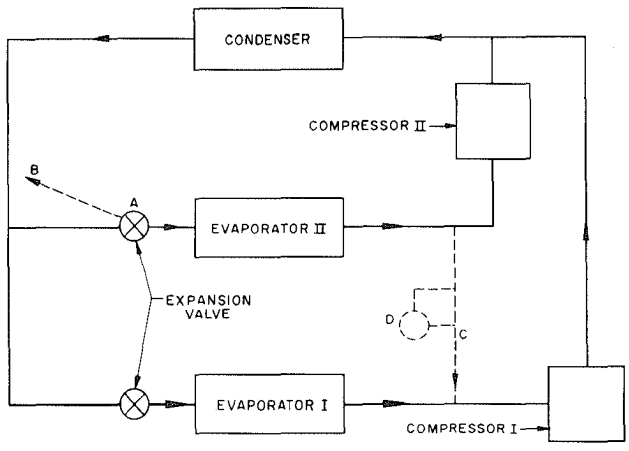

Fig. 13 Equipment Diagram for Two-Evaporator, Two-Compressor System

The *T-S* diagram is given in Figure 15. As the flow of refrigerant through each compressor is different, the liquid and vapor saturation lines are omitted.

State-Point Properties

State	p, psia	t, °F	h, Btu/lb	s, Btu/lb·°R

SECOND LAW ANALYSIS FOR OPTIMUM CYCLE DESIGN

The concepts of available and unavailable energy, degradation of available energy, and irreversibility are used by Patel (1969), Swers (1968), and Swers *et al.* (1972) to demonstrate a logical and systematic method for selecting a refrigeration cycle's optimum parameters. This method is described for both the basic vapor compression system and a two-stage compression system with desuperheating between compressor stages (intercooling) and subcooling of the liquid before the main expansion valve.

These examples describe the effects of irreversibilities in the refrigeration systems for a range of operating conditions, list the irreversibility of each cycle component, and compare irreversibilities and parameters of the two systems.

Figures 16 and 17 show the equipment designs of the cycles; *T-S* and *P-h* diagrams appear in Figures 18 and 19. To compare operations of the two systems, various points in the operations are identified by numbers consistent for all four figures. These numbers are used as subscripts in identifying pressures and temperatures throughout the system. M_1, M_2, M_3, and M_4 identify rates of refrigerant flow through the various circuits of the two-stage cycle.

In preparing these comparisons, the thermodynamic properties of R-12 were programmed for the computer from equations using the thermodynamic property relations given in the Thermodynamics section of this chapter. A computer program for the cycle analysis was used to calculate the results. The number of significant figures in the tabulated results is not justified on the basis of the data's uncertainty, but is presented to maintain consistency.

Refrigeration Cycle Specifications

The cycles analyzed here are defined in terms of refrigerant temperatures and pressures at various points in the cycles, and temperatures of refrigeration load and of the environment. These temperatures and pressures are specified to be independent of each other, *i.e.*, changes in any one specification are independent of other input parameters. Standard state operating conditions for these cycles are specified in Table 2. Effects of each of these parameters are identified by analyzing the cycle over a range of values for each specification. The determination of heat transfer and fluid flow characteristics in the system components are not considered in this analysis, but temperatures and pressures are given as input parameters that reflect the results of heat transfer and fluid flow characteristics.

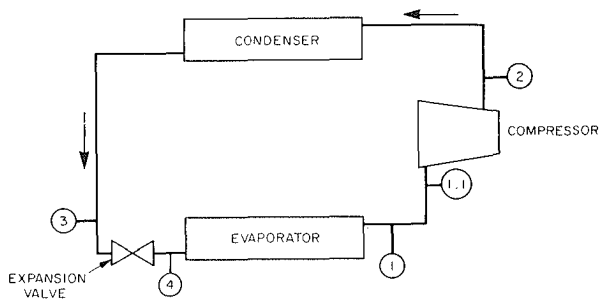

Fig. 16 Basic Vapor Compression System

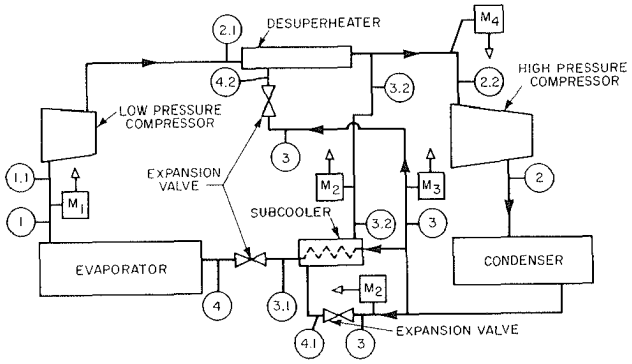

Fig. 17 Two-Stage Compression System

Table 2 Standard Operating Conditions

Item	Basic Vapor Compression System	Two-Stage Compression System
Refrigeration load temp. T_R, °F	0	0
Environment temp. T_o, °F	70	80
Efficiency of compressors, %	70	80
Temp. difference between refrigerant at condenser outlet and environment temp. $T_3 - T_o$, °F	5	5
Temp. difference between refrigeration load and refrigerant at evaporator outlet $T_R - T_1$, °F	5	5
Pressure drop between condenser inlet and outlet $p_2 - p_3$, psi	5	5
Pressure drop between evaporator inlet and outlet $p_4 - p_1$, psi	2	5
Pressure at condenser outlet p_3, psia	105	115
Pressure at evaporator outlet p_1, psia	17	19
Temp. increase of refrigerant between evaporator outlet and (low-pressure) compressor inlet $T_{1.1} - T_1$, °F	3	2
Pressure drop between evaporator outlet and (low-pressure) compressor inlet $p_1 - p_{1.1}$, psi	3	1
Pressure drop between inlet and outlet of desuperheater $p_{2.1} - p_{2.2}$, psi		1.5
Degrees of superheat at outlet of desuperheater $T_{sat} - T_{2.2}$, °F		5
Degrees of subcooling at subcooler outlet $T_{sat} - T_{3.1}$, °F		20
Temp. difference between subcooler vapor outlet and inlet $T_{3.2} - T_{3.1}$, °F		10

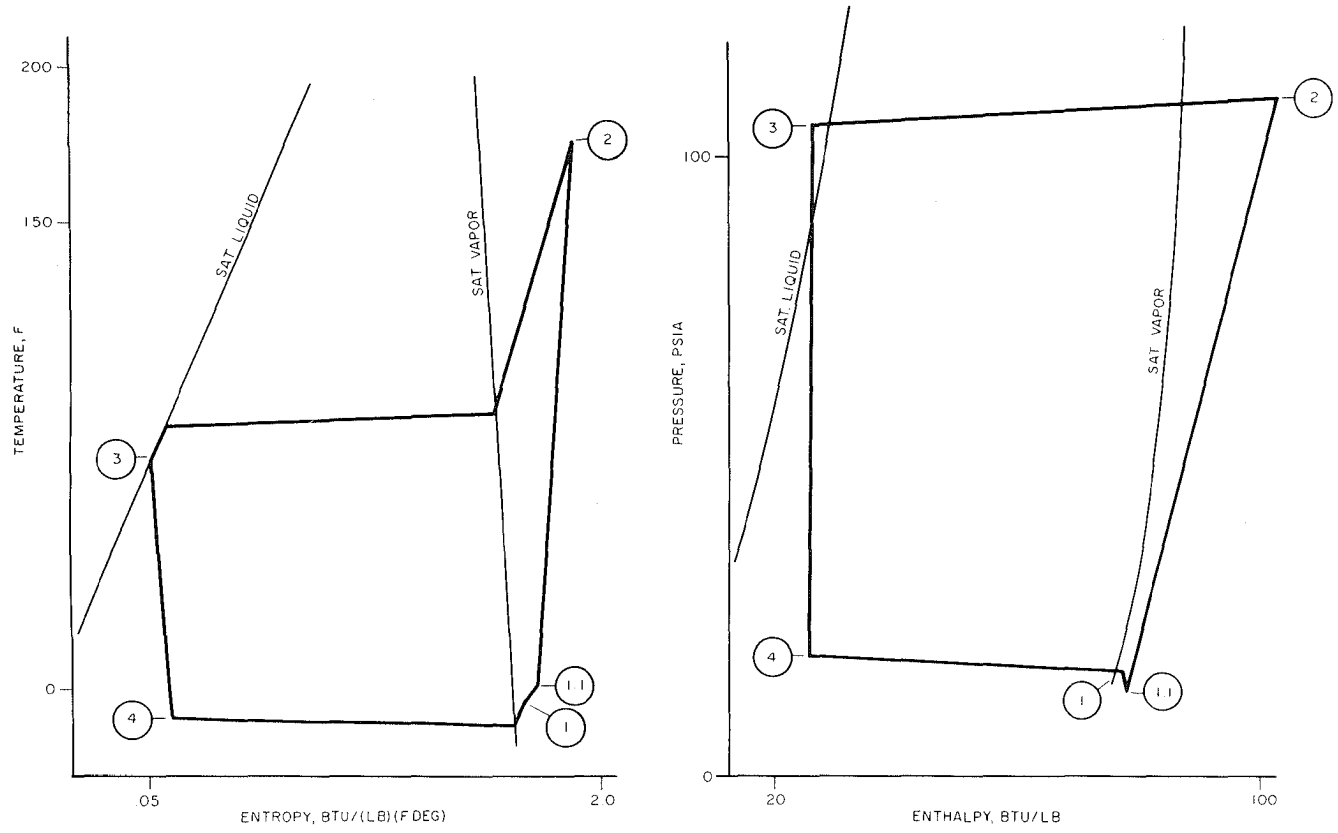

Fig. 18 Basic Vapor Compression Cycle

Selecting Intercooler Pressure for Two-Stage Compression Systems

As previously discussed, one design parameter of the two-stage compression system is selecting the interstage pressure. The total compressor work, given in Table 1, illustrates the effect of interstage pressure. However, the irreversibilities of the entire system may be a more valid basis for selecting this pressure, since a change in intercooler pressure affects conditions throughout the cycle. Table 3 presents values of irreversibilities for the system as a function of interstage pressure. In addition, it gives irreversibility of low- and high-pressure compressors and the work of compression (from Table 1) for comparison. In this example, the inlet pressure to the first stage compressor is 18 psia and the discharge pressure from the second stage is 120 psia, with the remaining cycle conditions as shown in Table 2. The values in Table 3 show that for this specific example, the minimum total work and the minimum total system irreversibility occur at a maximum intercooler pressure (*i.e.*, with single-stage compression).

This case differs from the case of two compressors in series where intercooling is provided by a separate coolant, since the refrigerant used for intercooling in this system causes irreversibilities. In addition, mass flow in the high-pressure compressor increases with decreasing intercooler pressure, since the refrigerant used for desuperheating is recycled to the second-stage compressor. These results also indicate that the low-pressure and high-pressure compressor work are equal at the interstage pressure of approximately 50 psia, whereas the geometric mean of the system's suction and discharge pressures is 46.47 psia. Under conditions in this example, the criterion of minimum work cannot be used to select the interstage pressure. Therefore, the following equations use geometric mean pressure, 46.47 psia, because it provides nearly equal volumetric efficiencies of the two stages.

Comparing Irreversibilities of Refrigeration Systems

The effects of changes in operating conditions of the basic compression refrigeration system and of the two-stage compression

refrigeration system were calculated for standard state conditions in Table 2 and then for operating conditions in which each specification of Table 2 was varied, one at a time, over a range of values.

These analyses made the following assumptions:

1. The refrigeration load temperature is constant.
2. The heat transferred from the condenser is discharged to the environment at temperature T_o.
3. In the two-stage cycle, the compressor efficiencies of the two stages are equal.
4. In both systems, the piping connecting the cycle components is adiabatic with negligible fluid friction, except for the pipe connecting the evaporator outlet to the low-pressure compressor inlet. (In many cases, these piping losses are considered to be combined with losses in adjacent components.)

Table 4 lists refrigerant properties at various points of the cycle for standard state operating conditions. Table 5 gives a sample calculation of the irreversibilities at standard state conditions.

Carnot work	30.46	30.46	34.81

*All units are Btu/min per ton of cooling.

The results of these second law analyses are expressed in terms of the irreversibilities various system components. Irreversibilities for both basic and two-stage systems are tabulated in Table 6 for standard state conditions. However, since operating conditions of the two systems are not identical, results for the two-stage compression system are given at (1) standard operating condition, where the environment temperature is 80°F and (2) at 70°F, which is the environment temperature for the standard operating condition of the basic vapor compression cycle.

Results given in Table 6 indicate that irreversibilities for each component of the two-stage compression system are smaller than for the basic cycle, and that total cycle irreversibility is about one-third less. In both systems, the largest irreversibilities occur in the compressor, and the next largest occur in the condenser. Losses in the expansion valve are significant but are the smallest of the major components. Piping loss for the basic system is large for the operating conditions chosen, whereas the pressure loss and temperature rise specified for the two-stage system result in smaller piping losses. Results such as those given in Table 6 should be weighed with the cost of larger heat exchangers, or improved compressors, to obtain an optimum economic design. This type of analysis for several different cycle configurations is useful in selecting an optimum configuration.

Table 7 lists the energy balance for these systems and includes mass flows for the two-stage system. (Note that total work listed in Table 7 is equal to the sum of the total irreversibility and the Carnot work given in Table 6.)

Tables 8 and 9 illustrate relative effects of the design parameters for a range of operating conditions in the basic compression cycle and the two-stage cycle, respectively. These tables show irreversi-

bilities of cycle components for Table 1 parameter values that differ from standard operating conditions. The following paragraphs address effects of some of the operating parameters in Tables 8 and 9. These paragraphs are numbered to correspond to the columns in Tables 8 and 9, which also correspond to the items given in Table 2.

Column 1. In both systems, changes in refrigeration load temperature affect the irreversibility of the evaporator. This change in irreversibility results from a change in temperature gradient across this heat exchanger (*i.e.*, the difference between temperatures of the refrigerant and of the refrigeration load). In these calculations, the refrigerant at the evaporator outlet is at a constant pressure, with the temperature 5 °F below load temperature.

Table 7 Energy Balance

	Basic System* (T_o = 529.7 °R)	Two-Stage System* (T_o = 529.7 °R)	Two-Stage System* (T_o = 539.7 °R)
Energy			
Heat from condenser	293.4	273.6	275.3
Work from L.P. compressor	—	33.0	33.0
Work from H.P. compressor	—	39.3	41.0
Total work	91.0	72.3	74.0
Desuperheater heat transfer by			
M_1	—	17.6	17.6
M_2	—	0.6	1.7
M_3	—	18.2	19.2
Subcooler heat transfer	—	8.5	17.1
Heat into pipe (1 to 1.1)	2.4	1.3	1.3
Mass Flow			
Flow through evaporator, M_1	—	3.703	3.703
Flow through subcooler, M_2	—	0.140	0.287
Flow for desuperheating, M_3	—	0.322	0.357
Flow through condenser, M_4	3.857	4.165	4.347

*All units are Btu/min per ton of cooling.

(The evaporator outlet pressure for the basic cycle is 17 psia; for the two-stage cycle, 19 psia.) Refrigerant temperature at the evaporator outlet is above the saturation temperature, and the degree of superheat depends on load temperature. Therefore, changes in load temperature affect the degree of superheat at the evaporator outlet. The inlet state to the evaporator is not affected by this change.

Column 1A. The change in load temperature with the refrigerant at the outlet state of the evaporator at a constant temperature of −5 °F affects only the irreversibility of the evaporator. With refrigerant properties throughout the system held constant, a change in load temperature does not affect irreversibilities of the other components.

Column 2. Changes in environment temperature affect the irreversibility of the condenser. In the basic cycle, the irreversibility of the expansion valve also changes with this variable. (This is not the case for the two-stage cycle.) The irreversibility of the condenser shows large variations with changes in environment temperature, because the inlet state of the condenser remains constant: therefore, the average temperature gradient across the heat exchanger varies with changes in environment temperature. In this calculation, the refrigerant at the condenser outlet is at a constant pressure and a temperature 5 °F above environment temperature. Outlet pressure for the basic cycle was 105 psia; for the two-stage cycle, 115 psia. In both cases, refrigerant temperatures at the condenser outlet are below their saturation temperatures. The change in irreversibility of the expansion valve for the basic cycle results from this temperature change at the inlet to the valve (which varies with environment temperature). This difference, due to liquid subcooling in the condenser, is insignificant for the two-stage cycle, since the separate subcooler eliminates much of this irreversibility. Note that at temperatures below 65 °F, mass flow from the subcooler outlet is zero, and the irreversibility of the subcooler is zero.

Column 2A. The effect of change in environment temperature is also given in Column 2A, but the condenser outlet temperature is held constant (at 75 °F for the basic cycle, and 85 °F for the two-stage cycle). The major difference in performance of both systems is the variation in irreversibility of the condenser. With no changes

Table 8 System Irreversibilities for Range of Design Parameters in Basic Compression Refrigeration System[a,b]
Irreversibilities are in Btu/min for a refrigeration rate of 200 Btu/min; temperatures are in °F and pressures in psia.

[a] Irreversibilities are in Btu/min; for a refrigeration rate of 200 Btu/min; temperatures are in °F; and pressures are in psia.
[b] "a" indicates that the irreversibility is the same as the standard condition.

in liquid subcooling in the condenser, irreversibility in the expansion valve for the basic system does not undergo large variation (see Column 2).

Column 3. Compressor irreversibility is directly proportional to compressor efficiency, and changes in efficiency affect irreversibility. An increase in compressor efficiency also causes a decrease in condenser irreversibility, since the temperature of the compressor outlet decreases with increases in efficiency, which changes the temperature gradient between the superheated vapor in the condenser and the surroundings. A similar effect is noted in performance of the desuperheater for the two-stage cycle. In this calculation, compressors are assumed to operate adiabatically, and compressor loss is identified by assuming an adiabatic efficiency.

Columns 4, 5, 6, 10, and 12. The effect on system performance from variation of the steady-state parameters numbered 4, 5, 6, 10, and 12 is small for the range of conditions shown in Tables 8 and 9. In some cases, the difference in the irreversibility of one component is offset by a similar difference in the opposite direction in another component.

Column 7. An increase in the evaporator pressure loss increases irreversibility of the evaporator but decreases irreversibility of the expansion valve ahead of the evaporator by the same amount; therefore, the total cycle irreversibility remains the same. Because the inlet state to the expansion valve ahead of the evaporator and the outlet state to the evaporator remain fixed, the same heat is removed from the evaporator, and there is no overall change in system performance. However, evaporator heat exchanger surface designs are affected, since the average temperature gradient between refrigerant and refrigeration load is changing.

Column 8. Varying condenser pressure primarily affects irreversibility of the condenser. An increase in compressor discharge pressure also increases irreversibility of the compressor, since work of compression is increased. This change in irreversibility results from change in condensation temperature, a function of condenser pressure.

Column 9. An increase in evaporator pressure decreases the irreversibility of every component in both of these systems. Evaporator pressure affects pressure difference across the expansion valve, compression required in the compressor, and discharge temperature from the compressor (the inlet temperature to the condenser). All changes result in differences in the irreversibilities of these units. There are similar variations in the additional components of the two-stage system. In the basic system, the irreversibility change in the evaporator is larger than for other components. In the two-stage system, the evaporator irreversibility is the largest of the components, but variations in other units are relatively small by comparison. The change in irreversibility of the evaporator is attributed to change in the temperature gradient between refrigerant and refrigeration load. In these calculations, evaporator outlet temperature is constant at $-5\,°F$.

Column 11. The effect of pressure drop in the compressor inlet piping is large compared to the effect of temperature rise (Column 10). Increased pressure loss increases piping irreversibility; large changes in compressor irreversibility are also noted.

Table 9 System Irreversibilities for Range of Design Parameters in Two-Stage Compression Refrigeration System[a,b]

[a]Irreversibilities are in Btu/min for a refrigeration rate of 200 Btu/min; temperatures are in °F; and pressures are in psia.

[b]"a" indicates that the irreversibility is the same as the standard condition.

Column 13. The effect of subcooling in the subcooler on system performance is primarily on the irreversibility of the subcooler and on the main expansion valve. Increased heat transfer in the subcooler results in a corresponding increase in its irreversibility. This is offset by the decrease in irreversibility of the expansion valve. Increasing the amount of subcooling decreases the total irreversibility of the system and changes irreversibility in other components.

Recommendations

These analyses illustrate a method of systems analysis; identifying sources of irreversibilities in a system provides a basis for selecting design parameters. However, optimum system design considers the cost of system components and then compares the cost of improving the performance of a given component with the cost of improving all other components in the system.

An extension of this work, the mathematical modeling of the system components, allows study of a given system for a range of steady-state operating conditions. An additional extension, the consideration of thermal properties of the system components, allows calculation of transient operating conditions.

ABSORPTION REFRIGERATION CYCLES

Absorption refrigeration cycles are heat-operated cycles in which a secondary fluid (the absorbent) absorbs the primary fluid (gaseous refrigerant) that has been vaporized in the evaporator.

In the basic absorption cycle, low-pressure refrigerant vapor is converted to a liquid phase (solution) while still at low pressure. Conversion is made possible by the vapor being absorbed by a secondary fluid—the absorbent. Absorption proceeds because of the mixing tendency of miscible substances, and because of an affinity between absorbent and refrigerant molecules. Thermal energy released during the absorption process must be released to a sink. This energy arises from the heat of condensation, sensible heats, and heat of dilution.

The refrigerant-absorbent solution is pressurized in the solution pump and conveyed via a heat exchanger to the generator where refrigerant and absorbent are separated, *i.e.*, regenerated, by a distillation process. A simple still is adequate for the separation when the pure absorbent material is nonvolatile, as in the water-lithium bromide system. However, fractional distillation equipment is required when the pure absorbent material is volatile, as in the ammonia-water system. Refrigerant that is not essentially free of absorbent hampers vaporization in the evaporator (Threlkeld 1970). The regenerated absorbent normally contains a substantial amount of refrigerant. If the absorbent material tends to become solid, as in the water-lithium bromide system, enough refrigerant must be present to keep the pure absorbent material in a dissolved state. Certain considerations, particularly avoiding excessively high temperatures in the generator, make it desirable to leave a moderate amount of refrigerant in the regenerated absorbent.

Figure 20a diagrams a basic absorption cycle that uses a lithium bromide and water solution as an absorbent and water as a refrigerant. Figure 20b shows state points of the pressure-temperature diagram for this pair in the basic absorption cycle. The flow path for these schematics is as follows:

Path 1-2. Hot, concentrated solution (1), in equilibrium with the condenser pressure, leaves the generator; this solution is cooled in the heat exchanger by the incoming solution and throttled to the absorber (2).

Path 2-4. Cold, concentrated solution (2) absorbs low-pressure refrigerant (8 and 9) in the absorber in equilibrium with the evaporator pressure.

Path 4-5. Solution (4) is pumped to the generator via the heat exchanger, where it is heated (5) by the solution leaving the generator.

Path 5-1. Hot, dilute solution (5) enters the generator, where heat is added to distill refrigerant (6). Hot, concentrated solution leaves the generator (1).

Path 6-7. Hot, high-pressure refrigerant vapor (6) condenses (7).

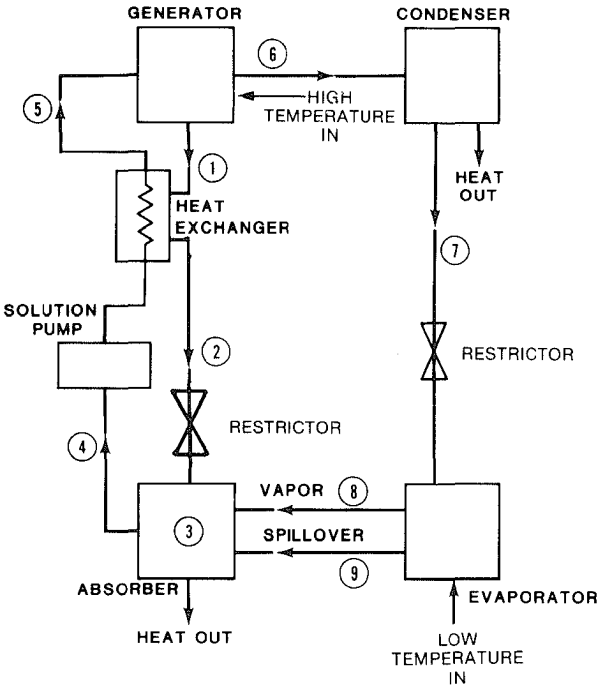

Fig. 20a Lithium Bromide-Water Single-Stage Absorption Refrigeration Cycle

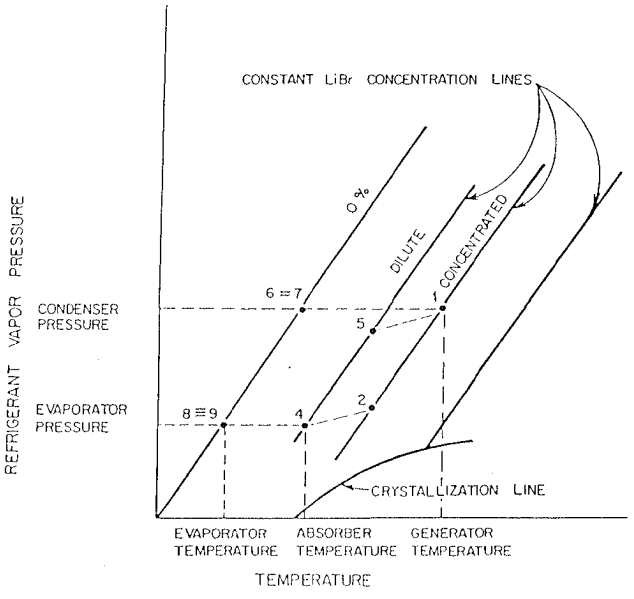

Fig. 20b Pressure-Temperature State Points for Lithium Bromide-Water Single-Stage Absorption Refrigeration Cycle

Path 7–8. Hot, liquid refrigerant is expanded into the evaporator, where it is evaporated at low pressure and temperature with heat from the cooled space. Cold, low-pressure refrigerant vapor (8) is absorbed by the solution in the absorber (3).

ABSORPTION CYCLES IN PRACTICE

Inefficiencies in the basic absorption cycle are caused by sensible heat lossees, heats of solution, and vaporization characteristics of the absorbing fluid. Conveying hot absorbent from generator into absorber wastes considerable thermal energy. A liquid-to-liquid heat exchanger transfers energy from this stream to the refrigerant-absorbent solution being pumped back to the generator, saving a major portion of the energy. Use of this liquid heat exchanger is shown in the flow diagram for a water-lithium bromide cycle (Figure 20a) and for an ammonia-water cycle (Figure 21).

Modifications for the basic cycle do not bring the coefficient of performance over a threshold of unity, *e.g.*, heat required to generate one pound of refrigerant is not less than the heat taken up when this pound evaporates in the evaporator. Performance can be improved by using the double-effect evaporation principle and a double-effect generator (Whitlow and Swearingen 1958). With the water-lithium bromide pair, two generators can be used: one, at high temperature and pressure, heated by an external source of thermal energy; a second, at lower pressure and temperature, heated by condensation of the vapor from the first generator. Condensate from both generators moves to the evaporator.

CHARACTERISTICS OF REFRIGERANT-ABSORBENT PAIR

The materials that make up the refrigerant-absorbent pair should meet the following requirements to be suitable for absorption refrigeration:

Absence of solid phase. The refrigerant-absorbent pair should not form a solid phase over the range of composition and temperature to which it might be subjected. If a solid forms, it presumably would stop flow and cause equipment shutdown.

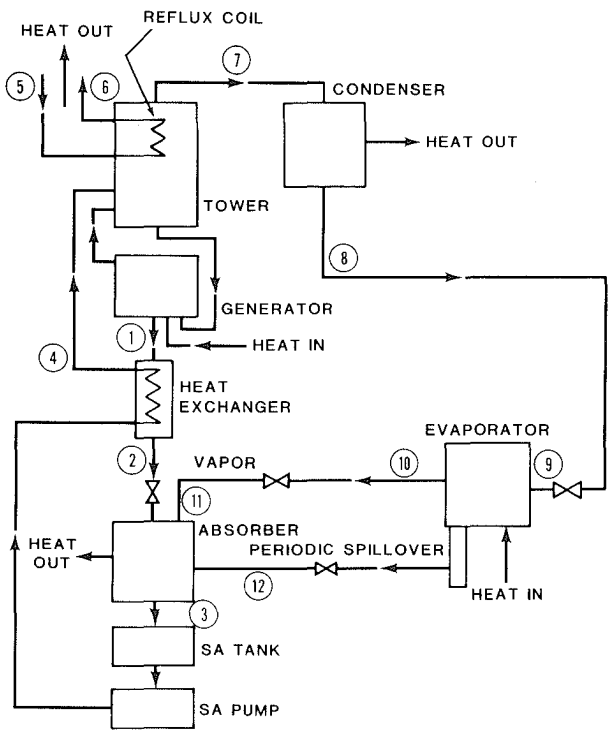

Fig. 21 Ammonia-Water Single-Stage Absorption Refrigeration Cycle

Volatility ratio. The refrigerant should be much more volatile than the absorbent so the two can be easily separated. Otherwise, cost and heat requirements can prohibit separation.

Affinity. The absorbent should have a strong affinity for the refrigerant under conditions in which absorption takes place (Buffington 1949). This affinity (1) causes a negative deviation from Raoult's law and results in an activity coefficient of less than unity for the refrigerant; (2) reduces the amount of absorbent to be circulated and, consequently, the waste of thermal energy from sensible heat effects; and (3) reduces the size of the liquid heat exchanger that transfers heat from absorbent to pressurized refrigerant-absorbent solution in practical cycles. Calculations by Jacob *et al.* (1969) indicate that strong affinity has disadvantages. This affinity is associated with a high heat of dilution; consequently, extra heat is required in the generator to separate refrigerant from absorbent.

Pressure. Operating pressures, largely established by physical properties of the refrigerant, should be moderate. High pressures necessitate use of heavy-walled equipment, and significant electrical power may be required to pump the fluids from low side to high side. Low pressures (vacuum) necessitate use of large volume equipment and special means of reducing pressure drop in refrigerant vapor flow.

Stability. Almost absolute chemical stability is required, because fluids are subjected to severe conditions over many years of service. Instability could cause the undesirable formation of gases, solids, or corrosive substances.

Corrosion. Since the fluids or substances created by instability can corrode materials used in constructing equipment, corrosion inhibitors should be used.

Safety. Fluids must be nontoxic and nonflammable if they are in an occupied dwelling. Industrial process refrigeration is less critical in this respect.

Transport properties. Viscosity, surface tension, thermal diffusivity, and mass diffusivity are important characteristics of the refrigerant and absorbent pair. For example, low viscosity of the fluid promotes heat and mass transfer and reduces pumping problems.

Latent heat. The refrigerant's latent heat should be high so the circulation rate of the refrigerant and absorbent can be kept at a minimum.

No known refrigerant-absorbent pair meets all requirements listed. Ammonia-water and water-lithium bromide are two pairs in extensive commercial use. The ammonia-water pair meets most requirements, but its volatility ratio is too low, and it requires high operating pressures. Furthermore, ammonia is a Safety Code Group 2 fluid (ASHRAE *Standard* 15-1989), restricting its indoor use.

Advantages of the water-lithium bromide pair include high safety, high volatility ratio, high affinity, high stability, and high latent heat. However, this pair tends to form solids. Since the refrigerant turns to ice at 32°F, the pair cannot be used for low-temperature refrigeration. Lithium bromide crystallizes at moderate concentrations, especially when it is air cooled, limiting the pair to applications where the absorber is water cooled. However, using a combination of salts as the absorbent can reduce this crystallizing tendency enough to permit air cooling (Macriss 1968, Weil 1968, and Rush 1968). Other disadvantages of the water-lithium bromide pair include the low operating pressures it requires and the lithium bromide solution's high viscosity. Proper equipment design can overcome these disadvantages.

Other important refrigerant-absorbent pairs include the following:

- Ammonia-salts (Blytas and Daniels 1962, Robertson *et al.* 1966)
- Methylamine-salts (Robertson *et al.* 1966, Macriss *et al.* 1969)

- Alcohols-salts (Aker *et al.* 1965)
- Ammonia-organic solvents (Robertson *et al.* 1966)
- Sulfur dioxide-organic solvents (Albright *et al.* 1963)
- Halogenated hydrocarbons-organic solvents (Albright *et al.* 1962, Albright *et al.* 1960, Albright and Thieme 1961, Hesselberth and Albright 1966)

Several pairs of refrigerant-absorbents appear suitable for a relatively simple cycle and may not create as much of a crystallization problem as the water-lithium bromide pair. However, stability and corrosion information on most of them is limited. Also, the refrigerants, except for fluororefrigerants in the last type, are somewhat hazardous. Adding corrosion inhibitors, crystallization retardants, or heat transfer enhancers may correct these problems.

THERMODYNAMIC ANALYSIS

First law analysis is useful for investigating new refrigerant-solvent pairs, improving cycles, finding effects of operating conditions, troubleshooting test equipment, and related studies. The method is illustrated in the following data on the water-lithium bromide and the ammonia-water machines. For convenience in making first law analyses and other calculations, see appropriate charts in Chapter 17.

Second law analysis is useful for quantifying the inefficiencies, or thermodynamic irreversibilities, of each process in a cycle. In such an analysis, the concept of availability—a measure of the work that could be produced from a flow stream if it were carried in an ideal reversible manner to an equilibrium condition with the environment—is used. For instance, the availability of a hot fluid stream is work that could be produced by cooling and expanding that fluid to atmospheric temperature and pressure while converting the resulting heat flow to work by an ideal Carnot cycle and the fluid expansion to work by an ideal expansion turbine. The loss of availability by irreversibilities in a process can never be recovered. The principal irreversibilities leading to this loss are heat transfer through a large temperature difference, friction, and unrestrained expansion. Availability is a state function or property. If kinetic and potential energy are negligible, availability is calculated from:

$$B = h - h_o - T_o (S - S_o) \tag{66}$$

where

B = availability per unit mass
h = enthalpy per unit mass
h_o = enthalpy at ambient conditions
T_o = ambient absolute temperature
S = entropy per unit mass
S_o = entropy at ambient conditions

Second law analysis of absorption cycle machines generally shows that the generator produces the largest loss of availability.

WATER-LITHIUM BROMIDE MACHINE

The determination of essential fluid flow rates is based on the following relationships (Figure 20):

$$R_E = Q_E/(h_v - h_l) \tag{67}$$

where (in consistent units)

R_E = mass flow of refrigerant from evaporator
Q_E = heat load at evaporator
h_v = enthalpy of refrigerant vapor from evaporator
h_l = enthalpy of refrigerant liquid from condenser

$$R_A X - R_G (X - 1) = 1 \tag{68}$$

where

R_A = refrigerant mass fraction in solution leaving absorber
R_G = refrigerant mass fraction in solution leaving generator
X = mass of solution flow from absorber/unit mass flow rate of refrigerant
$X - 1$ = mass of solution flow from generator/unit mass flow rate of refrigerant
l = unit mass flow of refrigerant

In this equation, the refrigerant in the dilute solution (from the absorber) minus the refrigerant in the concentrated solution from the generator equals the unit mass flow of refrigerant being considered.

This equation can be rewritten:

$$(1 - WFS_A) X - (1 - WFS_G) (X - 1) = 1 \tag{69}$$

where

WFS_A = mass fraction of lithium bromide in solution from absorber
WFS_G = mass fraction of lithium bromide in solution from generator

Therefore, if the concentrations of lithium bromide are $WFS_A = 0.595$ and $WFS_G = 0.646$, Equation (69) becomes:

$$(1 - 0.595) X - (1 - 0.646) (X - 1) = 1$$
$$0.405 X - 0.354 (X - 1) = 1$$
$$\text{and } X = 12.67$$

Flow rates can be developed for a hypothetical system with certain assumptions or prior knowledge of typical system conditions as in the following example:

Example 5. A large lithium bromide machine operating according to the flow diagrams of Figures 20a and 20b (including identifying numbers) has the following conditions:

1. Refrigeration load, 500 tons
2. Evaporator temperature (point 8), 41.1°F
3. Absorber equilibrium temperature (point 3), 107.2°F
4. Actual solution temperature (point 4), 100.9°F
5. Solution temperature (point 5), 170.3°F
6. Solution temperature (point 1), 209.6°F
7. Solution temperature (point 2), 128.1°F
8. Refrigerant vapor temperature (point 6), 200°F
9. Refrigerant temperature (point 7), 110°F
10. Refrigerant spillover rate (point 9), 2.5% of (point 8)
11. Concentrations of solution per above
12. Chilled water temperatures, 54 – 44°F
13. Cooling water temperature entering, 85°F
14. Assume no inerts present
15. Cooling tower water flow rate, 1800 gpm

The lithium bromide charts in Chapter 17 and the steam tables in Keenan *et al.* (1969) may be used to find fluid flow rates, heat loads for the various components, and the COP for the system.

Enthalpy	Btu/lb
Of (8), h_v =	1079.8
Of (7), h_l =	77.94
Difference, ΔH =	1001.86

$$1.025 \frac{500 \text{ tons} \times 200}{1001.86} = 102.3 \text{ lb/min refrigerant}$$

12.67×102.3 = 1296.14 lb/min dilute solution
− 102.3 lb/min refrigerant
1193.84 lb/min concentrated solution

Approximate absolute pressure at generator = 65.9 mm Hg

Enthalpy	Btu/lb
Of (9) h_l	9.15
Of (2) h_l	71.7
Of (4) h_l	47.2
Of (5) h_l	79
Of (1) h_l	107
Of (6) h_v	1150.3

Material and heat balances at each component follow:

Absorber

Heat in		Btu/min
(2) 1193.84 × 71.7	=	85,598.3
(8) (102.3/1.025) (1079.8)	=	107,769.3
(9) (102.3/1.025) (0.025) (9.15)	=	22.8
Subtotal	=	193,390.4
Heat out		
(4) 1296.14 × 47.2	=	61,177.8
Absorber load (difference)	=	132,212.6

Generator

Heat out		Btu/min
(1) 1193.84 × 107	=	127,741
(6) 102.3 × 1150.3	=	117,676
Subtotal	=	245,417
Heat in		
(5) 1296.14 × 79	=	102,395
Generator load (difference)	=	143,022

Condenser

Heat in		Btu/min
(6) 102.3 × 1150.3	=	117,676
Heat out		
(7) 102.3 × 77.94	=	7,973
Condenser load (difference)	=	109,703

Evaporator

500 tons × 200 = 100,000 Btu/min

Heat Balance

Heat in		Btu/min
Evaporator load	=	100,000
Generator load	=	143,022
Subtotal	=	243,022
Heat out		
Absorber load	=	132,213
Condenser load	=	109,703
		241,916
Balance within	=	0.46%

$$\text{COP} = \frac{\text{Evaporator Load}}{\text{Generator Load}} = \frac{100{,}000}{143{,}022} = 0.699$$

With 2% heat loss to ambient, COP = 0.685

The rate of steam flow or hot water flow to the generator can be determined by the enthalpies of steam and hot water available with assumed condensate and hot water temperatures off the generator. For saturated steam at 24.7 psia and 4 °F, subcooling of steam condensate in the generator, the steam rate is:

$$\frac{143{,}022 \times 1.02 \times 60}{(1160.3 - 203.7) \times 500} = 18.3 \text{ lb/h per ton}$$

and for hot water at 240 °F with a 10 °F water range, the flow rate of hot water is:

$$\frac{143{,}022 \times 1.02 \times 0.01692 \text{ ft}^3/\text{lb} \times 7.48 \text{ gal/ft}^3}{(208.34 - 198.23) \times 500 \text{ tons}} = 3.66 \text{ gal/min per ton measured at 240 °F}$$

The actual temperatures of the generator's heat source vary with the design heat transfer surface available and the application. For lower temperatures of steam or hot water, the concentrations of lithium bromide-water solutions and the COP are reduced for the same delivered chilled water temperature and available cooling tower water temperature. At lower cooling tower water temperatures, the concentrations and COP can be maintained, even though the available heat source temperature for the generator is reduced, within the practical limits for a given design.

AMMONIA-WATER CYCLE

Figure 21 diagrams an ammonia-water single-stage refrigeration cycle. This resembles a lithium bromide-water refrigeration cycle except, in large systems, the relative volatilities of ammonia and water require a fractional distillation accomplished with a packed tower, a bubble tower, or a tower with sieve trays. Reflux purifies the ammonia vapors coming off the top of the tower and assures the least possible water content of the refrigerant. The concentrated solution of ammonia-in-water (aqua), after being heated by the heat exchanger, is fed at some intermediate point generally near the lower portion of the tower (or rectifier/analyzer). The same required evaporator duty should be assumed when analyzing the system and comparing it with a lithium bromide-water cycle.

In smaller systems, the degree of ammonia vapor purity off the top of the tower (or rectifier/analyzer) is generally less than that in the following example. As a result, tower and condenser pressure is less, but water contamination of the refrigerant must be constantly bled by liquid spillover from the evaporator to the absorber. (In larger systems, a high purity of ammonia vapor off the tower is maintained, and spillover from the absorber can be a periodic occurrence.) To bleed refrigerant, the valve in the vapor line off the evaporator is throttled to establish a slight pressure differential between the evaporator and the absorber. Then, the valve in the liquid spillover line is cracked open until the ammonia in the evaporator is purified sufficiently (detected by checking the pressure in the evaporator versus the temperature of the liquid in the evaporator).

In large systems, a vertical liquid leg under the evaporator provides a relatively inactive area and accumulates ammonia rich in water. The spillover line is tapped into this liquid leg. At an evaporator pressure of 75 psia, a 10% by mass water content increases the refrigerant temperature from 41.1 to 45.8 °F for a 4.7 °F penalty (Jennings and Shannon 1938). For pure ammonia off the top of the tower (attained by keeping the superheat near 7 °F), the operating pressure and temperatures for the tower, generator, and condenser are relatively high, established by the coolant temperature available at the condenser.

In lithium bromide-water systems, the cooling tower water is fed to the absorber and then to the condenser. In ammonia-water systems, the cooling tower water is fed first to the condenser and then to the absorber. In both cases, coolant can be in parallel to improve efficiencies; however, this requires high coolant flow rates and excessively large cooling towers.

In the ammonia-water cycle, the reflux can be created by a separate condenser or by the main condenser. Reflux can flow by gravity or pump to the tower. Ammonia-water systems do not have the potential crystallization of solution problem of lithium bromide-water systems, and the controls can be simpler. Also, the corrosion characteristics of ammonia-water solutions are less severe, although inhibitors are generally used for both types of systems. Whereas lithium bromide-water systems use combinations of steel, copper, and copper-nickel materials for shells and heat transfer surfaces, no copper-bearing materials can be used in ammonia-water systems.

For the ammonia-water cycle, Equation (67) determines the refrigerant flow rate, and Equation (70) develops the solution flow rate per unit refrigerant rate:

$$WFS_A\,(X) - WFS_G\,(X - 1) = 1 \qquad (70)$$

where

WFS_A = mass fraction of ammonia in solution from absorber
WFS_G = mass fraction of ammonia in solution from generator
X = mass of solution from absorber per unit mass of refrigerant flow
$X - 1$ = mass of solution from generator per unit mass of refrigerant flow

For large systems, a reasonable pressure drop between the evaporator and absorber is 1.5 psi.

Example 6. A large ammonia-water absorption plant operating according to the flow diagram of Figure 21 has the following conditions:

1. Refrigeration load, 500 tons
2. Evaporator temperature (point 10), 41.1°F
3. Evaporator pressure (point 10), 75 psia
4. Absorber pressure (point 11), 73.5 psia
5. Strong aqua solution temperature (point 3), 105°F
6. Condenser temperature (point 8), 100°F
7. Condenser and tower pressure (point 7), 211.9 psia
8. Concentration split ($WFS_G - WFS_A$), 6% by mass
9. Cooling tower water temperature, 85°F

Chapter 17 shows the enthalpy-concentration diagram for ammonia-water mixture and the ammonia (R-717) properties table. Assume a 3% increase in the theoretical refrigerant flow rate to accommodate heat losses from the high-temperature shells and heat gain through insulation for the evaporator.

From the ammonia-water diagram at 73.5 psia and 105°F from the absorber, assuming no subcooling of solution, the strong aqua (SA) has a concentration of 49% by mass of ammonia. A 6 to 8% concentration split allows sufficient flow and adequate wetting of plain horizontal tubes up to 1 in. in diameter in optimum arranged absorbers when using gravity feed for large systems. It also ensures reasonable maximum liquid flows for cost-effective exchangers and towers and a practical minimum temperature of heat source for the generator. Large splits reduce the flow rate, efficiency, and cost-effectiveness of absorbers and exchangers and raise the required temperature of the heat source, unless a device minimizing these effects (a solution-cooled absorber) is used. With a 6% split, the concentration of ammonia in the weak aqua (WA) from the generator or tower will be 43% by mass. At a 30% split, the concentration of WA will be 19% by mass ammonia. Use of Equation (70) develops the solution flow rates:

For 6% split:

$$\begin{aligned} 0.49\,X - 0.43\,(X - 1) &= 1 \\ 0.49\,X - 0.43\,(X - 1) &= 1 \\ 0.06\,X + 0.43 &= 1 \\ \text{or } X = 0.57/0.06 &= 9.5 \\ X - 1 &= 8.5 \end{aligned}$$

For 30% split:

$$\begin{aligned} 0.49\,X - 0.19\,(X - 1) &= 1 \\ 0.30\,X + 0.19 &= 1 \\ \text{or } X = 0.81/0.30 &= 2.7 \\ X - 1 &= 1.7 \end{aligned}$$

The SA is heated to within 3°F of equilibrium in the tower to avoid flashing in the feed valve to the generator. Consequently, overpressurizing the SA is avoided, reducing the energy and head requirements for the SA pump. The equilibrium temperature of 49% aqua at 211.9 psia is 176.9°F. Therefore, the SA temperature to the tower is 173.9°F. For the 6% split, the 43% WA leaves the tower or generator at an equilibium temperature of 194.9°F. For the 30% split, the 19% WA leaves the tower or generator at an equilibrium temperature of 292°F. Enthalpy values to the aqua are as follows:

Enthalpy	6% Split, Btu/lb	30% Split, Btu/lb
of (1) h_l	71.4	218.7
of (4) h_l	48.3	48.3
of (3) h_l	−28.3	−28.3

The enthalpy of (2) h_l is determined by a mass-enthalpy flow rate balance, as follows:

For 6% split (43% WA):

$$71.4 - 9.5\,[48.3 - (-28.3)]/8.5 = -14.21 \text{ Btu/lb}$$

For 30% split (19% WA):

$$218.7 - 2.7\,[48.3 - (-28.3)]/1.7 = 97.04 \text{ Btu/lb}$$

These enthalpy values correspond to the following temperatures for solution entering the absorbers: for 6% split—118°F; for 30% split—181.5°F.

For a given strong ammonia (SA) concentration, tower pressure and feed temperature, and purity of ammonia produced in the main condenser at a given tower pressure, there is a minimum reflux rate to the top of the tower that requires an infinite number of trays or infinite tower height. For ammonia water mixtures using the enthalpy-concentration diagram of IGT (1964) and the procedure of Brown and Associates (1956), this minimum reflux ratio for 49% SA at the feed condition of 173.9°F for the tower pressure of 211.9 psia is 0.145 lb/lb of 99.95% ammonia refrigerant feed to the evaporator. The practical reflux rate for a reasonable tower height is at least 1.15 times this ratio or 0.167 lb/lb refrigerant.

By constructing flow lines for fluid streams entering and leaving the tower, generator, and condenser, the combined condenser and reflux coil loads, as well as the generator load, can be determined with a mass enthalpy balance calculation (Figure 22).

Enthalpy	Btu/lb
of (point 7) h_v	638.7
of (point 10) h_v	623.02
of (point 8) h_l	155.20
Difference (10 − 8) Δh	467.82

Refrigerant flow rate:

$$1.03 \times 500 \text{ tons} \times 12{,}000/467.82 = 13210.2 \text{ lb/h}$$

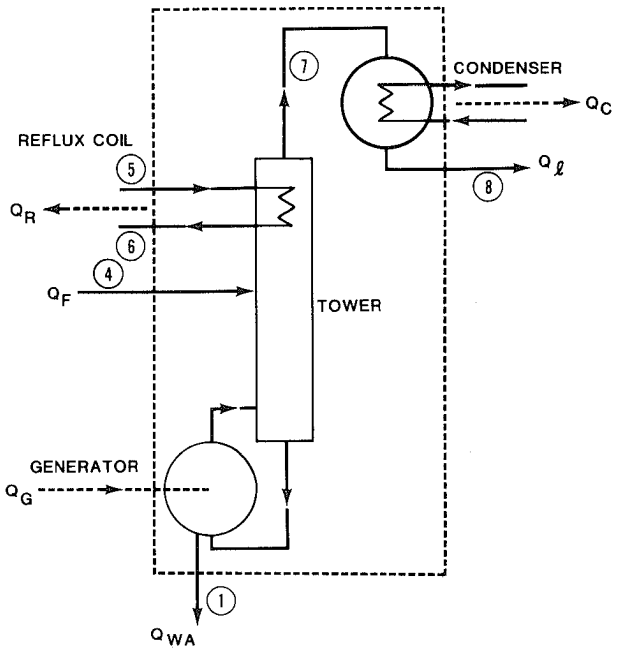

Fig. 22 Enthalpy Balance Method

Generator Heat

For 6% split:

Heat Out		Btu/h
Q_l	13,210.2 × 155.2	2,050,223
Q_c	13,210.2 × (638.7 − 155.2)	6,387,132
Q_r	0.167 × 13,210.2 × (638.7 − 155.2)	1,066,651
	Subtotal of $Q_l + Q_c + Q_r$	9,504,006
Q_{wa}	8.5 × 13 210.2 × 71.4	8,017,270
	Total heat out	17,521,276
Heat In		
Q_f	9.5 × 13,210.2 × 48.3	6,061,500
Q_g	Difference, generator heat	11,459,776

For 30% split:

Heat Out		Btu/h
	Subtotal of $Q_l + Q_c + Q_r$	9,504,006
Q_{wa}	1.7 × 13,210.2 × 218.7	4,911,420
	Total heat out	14,415,426
Heat In		
Q_f	2.7 × 13,210.2 × 48.3	1,722,742
Q_g	Difference, generator heat	12,692,684

Absorber Load (see Figure 21)

For 6% split:

Heat In		Btu/h
(point 11)	13,210.2 × 623.02	8,230,219
(point 2)	8.5 × 13,210.2 × (−14.21)	−1,595,594
	Subtotal heat in	6,634,625
Heat Out		
(point 3)	9.5 × 13,210.2 × (−28.3)	−3,551,562
Q_a	Difference, absorber load	10,186,187

For 30% split:

Heat In		Btu/h
(point 11)	13,210.2 × 623.02	8,230,219
(point 2)	1.7 × 13,210.2 × 97.04	2,179,260
	Subtotal heat in	10,409,479
Heat Out		
(point 3)	2.7 × 13,210.2 × (−28.3)	−1,009,391
Q_a	Difference, absorber load	11,418,870

Heat Balance

	6% Split	30% Split
Heat In	Btu/h	Btu/h
Evaporator	6,180,000	6,180,000
Generator	11,459,776	12,692,684
	17,639,776	18,872,684
Heat Out		
Condenser	6,387,132	6,387,132
Reflux coil	1,066,651	1,066,651
Absorber	10,186,167	11,418,870
	17,639,950	18,872,653
COP =	6,180,000 / 1.03 × 11,459,776	6,180,000 / 1.03 × 12,692,684
or	0.524	0.473

The most cost-effective cooling water system, condensers, and absorbers determine the cooling tower water flow rate. In the ammonia-water cycle, an 1800 gpm cooling water rate raises the temperature 19.6 °F for a 6% split and 21.0 °F for a 30% split in concentration. This is about a 25% greater range than for the lithium bromide-water cycle operating at the same evaporator temperature.

A large conventional flooded water cooler in the ammonia system of the example using plain steel tubes produces chilled water with a temperature about 5 °F above that for the lithium bromide-water cycle described earlier. For 44 °F chilled water and a lower ammonia evaporator temperature, the procedure in the example should be used to adjust the cycle's operating temperatures and COP.

CHAPTER 2

FLUID FLOW

Fluid Properties 2.1
Basic Relations of Fluid Dynamics 2.1
Basic Flow Processes 2.3
Flow Analysis 2.7
Noise from Fluid Flow 2.13

FLOWING fluids in heating, ventilating, air-conditioning, and refrigeration systems transfer heat or mass (as particles). This chapter introduces those basic fluid mechanics that are related to HVAC processes, reviews pertinent flow processes, and presents a general discussion of single-phase fluid flow analysis.

FLUID PROPERTIES

Fluids differ from solids in their reaction to shearing. When placed in shear stress, a solid deforms only a finite amount, whereas a fluid deforms continuously for as long as the shear is applied. A fluid is either a liquid or a gas. Although liquids and gases differ strongly in the nature of molecular actions, their primary mechanical differences are in the degree of compressibility and liquid formation of a free surface (interface).

Fluid motion can usually be described by one of several simplified modes of action or models. The simplest is the ideal-fluid model that assumes no resistance to shearing; flow analysis is well developed (Baker 1983, Schlichting 1979, Streeter and Wylie 1979) and when properly interpreted, is valid for a wide range of applications. Nevertheless, the effects of viscous action may need to be considered. Most fluids in HVAC applications can be treated as Newtonian, where the deformation is directly proportional to the shearing stress. Turbulence, which complicates fluid behavior, does not depend on the viscous nature of a fluid; although viscosity does tend to influence turbulence.

Density

Density ρ, or the mass per unit volume, is involved in most fluid models. The densities of air and water at standard conditions of 68 °F and 14.696 psi (sea level atmospheric pressure) are:

$$\rho_{water} = 62.3 \text{ lb}_m/\text{ft}^3$$

$$\rho_{air} = 0.075 \text{ lb}_m/\text{ft}^3$$

Viscosity

Viscosity is the resistance of adjacent fluid layers to shear. For shearing between two parallel planes, each of area A and separated by distance Y, the tangential force F per unit area required to slide one plate with velocity V parallel to the other is proportional to V/Y.

$$F/A = \mu (V/Y)$$

where the proportionality factor μ is the viscosity of the fluid. The ratio of the tangential force F to area A is the shearing stress τ;

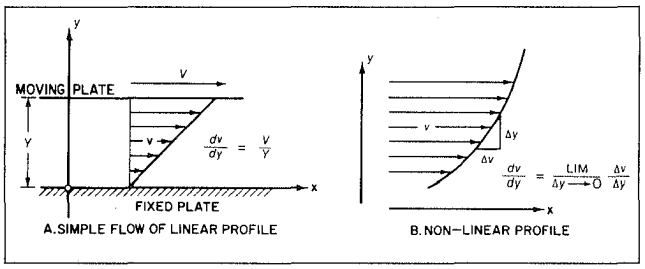

Fig. 1 Velocity Profiles and Gradients in Shear Flows

while V/Y is the lateral velocity gradient (Figure 1A). In complex flows, velocity and shear stress may vary across the flow field; this concept is expressed by the following differential equation:

$$\tau = \mu(dv/dy) \quad (1)$$

The velocity gradient associated with viscous shear for a simple case involving flow velocity in the x direction but of varying magnitude in the y direction is illustrated in Figure 1B.

Viscosity μ depends primarily on temperature. For gases (except near the critical point), viscosity increases with the square root of the absolute temperature, as predicted by the kinetic theory. Liquid viscosity decreases with increasing temperature. Viscosities of various fluids are given in Chapter 37.

At standard conditions, the viscosities of water and air are:

$$\mu_{water} = 6.7 \times 10^{-4} \text{ lb}_m/\text{ft}\cdot\text{s or } 2.1 \times 10^{-5} \text{ lb}_f\cdot\text{s}/\text{ft}^2$$

$$\mu_{air} = 1.2 \times 10^{-5} \text{ lb}_m/\text{ft}\cdot\text{s or } 3.7 \times 10^{-7} \text{ lb}_f\cdot\text{s}/\text{ft}^2$$

The centipoise is another common unit of viscosity (1 centipoise = 1 g/(s·m) = 1 mPa/s). Water at standard conditions has a viscosity close to 1.0 centipoise.

In fluid dynamics, *kinematic viscosity* ν is the ratio of viscosity to density, or $\nu = \mu/\rho$. The stoke (1 cm^2/s) or centistoke (1 mm^2/s) are common units for kinematic viscosity. At standard conditions:

$$\nu_{water} = 1.08 \times 10^{-5} \text{ ft}^2/\text{s}$$

$$\nu_{air} = 1.7 \times 10^{-4} \text{ ft}^2/\text{s}$$

BASIC RELATIONS OF FLUID DYNAMICS

This section considers homogeneous, constant-property, incompressible fluids and introduces fluid dynamic considerations of most analyses.

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Continuity

Conservation of matter applied to fluid flow in a conduit requires that:

$$\int \rho v dA = \text{constant}$$

where v, the velocity normal to the differential area dA and ρ, the density, may vary over the cross section A of a conduit. If both ρ and v are constant over the cross-sectional area normal to the flow, then:

$$\dot{m} = \rho V A = \text{constant} \tag{2a}$$

where $\dot{m}$ = mass flow rate across the area normal to the flow. When flow is effectively incompressible, ρ = constant; in pipeline and duct flow analyses, the average velocity is then $V = (1/A)\int v dA$. The continuity relation is:

$$Q = AV = \text{constant} \tag{2b}$$

Except when branches occur, the flow rate Q is the same at all sections along the conduit.

For the ideal-fluid model, flow patterns around bodies (or in conduit section changes) result from displacement effects. An obstruction in a fluid stream, such as a strut in a flow or bump on the conduit wall, pushes the flow smoothly out of the way, so that behind the obstruction, the flow becomes uniform again. The effect of fluid inertia (density) appears only in pressure changes.

Pressure Variation across Flow

Pressure variation in fluid flow is important and can be easily measured. Variation across streamlines involves fluid rotation (vorticity). Lateral pressure variation across streamlines is given by the relation (Bober and Kenyon 1980, Olson 1980, Robertson 1965):

$$\frac{\delta}{\delta r}\left(\frac{p}{\rho} + gz\right) = \frac{v^2}{r} \tag{3}$$

where r is the radius of curvature of the streamline. This relation explains the pressure difference found between the inside and outside walls of a bend and near other regions of conduit section change. It also states that pressure variation is hydrostatic ($p + \rho gz$ = constant) across any conduit where streamlines are parallel.

Bernoulli Equation and Pressure Variation along Flow

A basic tool of fluid flow analysis is the Bernoulli relation involving the principle of energy conservation along a streamline. Generally, the Bernoulli equation is not applicable across streamlines. The first law of thermodynamics is applied to mechanical flow energies (kinetic and potential) and thermal energies: heat is a form of energy and energy is conserved.

The change in energy content ΔE per unit mass of flowing material results from work W done on the system plus absorbed heat:

$$\Delta E = W + Q$$

Fluid energy is composed of kinetic, potential (as due to elevation z), and internal (u) energies. Per unit mass of fluid, the above energy change relation between two sections of the system is then:

$$\Delta\left(\frac{v^2}{2} + gz + u\right) = E_M - \Delta\left(\frac{p}{\rho}\right) + Q$$

The work terms are: (1) external work from a fluid machine E_M (positive for a pump or blower) and (2) pressure or flow work p/ρ. Rearranged, the energy equation can be written as the *generalized Bernoulli equation*:

$$\Delta\left(\frac{v^2}{2} + gz + \frac{p}{\rho}\right) + \Delta u = E_M + Q \tag{4}$$

The bracketed factor in Equation (4) is the Bernoulli *constant*:

$$\frac{p}{\rho} + \frac{v^2}{2} + gz = \pi \tag{5a}$$

In cases with no viscous action and no work interaction, π is constant; more generally its change (or lack thereof) is considered in applying the Bernoulli equation. The terms making up π are fluid energies (pressure, kinetic, and potential) per mass rate of fluid flow. Alternative forms of this relation are obtained through multiplication by ρ or division by g, thus:

$$p + \frac{\rho v^2}{2} + \rho gz = p + \frac{\rho v^2}{2} + \gamma z = \rho\pi \tag{5b}$$

$$\frac{p}{\rho g} + \frac{v^2}{2g} + z = \frac{p}{\gamma} + \frac{v^2}{2g} + z = \frac{\pi}{g} \tag{5c}$$

The first form involves energies per volume flow rate or pressures; the second involves energies per mass flow rate or heads. In gas flow analysis, Equation (5b) is often used with the γz term dropped as negligible. Equation (5a) should be used when density variations occur. For liquid flows, Equation (5c) is commonly used. Identical results are obtained with the three forms if units and fluids are homogeneous.

Many systems of pipes or ducts and pumps or blowers can be considered as one-dimensional flow. The Bernoulli equation is considered as velocity and pressure vary along the conduit. Analysis is adequate in terms of the section-average velocity V of Equation (2a) or (2b). The Bernoulli relation [Equations (4) and (5)] has v replaced by V, and variation across streamlines can be ignored; the whole conduit is now taken as one streamline. Two- and three-dimensional details of local flow occurrences are still significant, but their effect is accounted for in lumped factors.

The kinetic energy term of the Bernoulli constant is expressed as $\alpha V^2/2$ where the kinetic energy factor ($\alpha > 1$) expresses the true kinetic energy of the velocity profile in ratio to that of the mean flow velocity.

Heat transfer may often be ignored. The change of mechanical energy into internal energy Δu may be expressed as E_L. Flow analysis involves the change in the Bernoulli constant ($\Delta\pi = \pi_2 - \pi_1$) between stations 1 and 2 along the conduit, and the Bernoulli equation is expressed as:

$$\left(\frac{p}{\rho} + \alpha\frac{V^2}{2} + gz\right)_1 + E_M = \left(\frac{p}{\rho} + \alpha\frac{V^2}{2} + gz\right)_2 + E_L \tag{6a}$$

or in the head form

$$\left(\frac{p}{\gamma} + \alpha\frac{V^2}{2g} + z\right)_1 + H_M = \left(\frac{p}{\gamma} + \alpha\frac{V^2}{2g} + z\right)_2 + H_L \tag{6b}$$

The factors $gH_M = E_M$, representing energy added to the conduit flow by pumps or blowers; and $gH_L = E_L$, energy dissipated (converted into heat, as mechanically nonrecoverable energy), are defined as positive. A turbine or fluid motor thus has a negative

H_M or E_M. For conduit systems with branches involving inflow or outflow, the total energies must be treated; analysis is in terms of $\dot{m}\,\pi$ and not π.

When real-fluid effects of viscosity or turbulence are included, the continuity relation [Equation (2)] is not changed, but V must be evaluated from the integral of the velocity profile, using time-averaged local velocities.

In fluid flow past fixed boundaries, the velocity at the boundary is zero and shear stresses are produced. The equations of motion then become complex and exact solutions are difficult to find, except in simple cases.

Laminar Flow

For steady, fully developed laminar flow in a parallel-walled conduit, the shear stress varies linearly with distance y from the centerline. For a wide rectangular channel:

$$\tau = (y/b)\tau_w = m(dv/dy)$$

where τ_w = wall shear stress = bdp/ds.

Here the wall spacing is $2b$ and s is the flow direction. Since the velocity is zero at the wall ($y = b$), the integrated result is:

$$v = [(b_2 - y_2)/2\mu]dp/ds$$

This is the *Poiseuille-flow* parabolic velocity profile for a wide rectangular channel. The average velocity V is two-thirds the maximum velocity (at $y = 0$) and the longitudinal pressure drop in terms of conduit flow velocity is:

$$dp/ds = -(3\mu V/b^2) \tag{7}$$

The parabolic velocity profile can also be derived for the axisymmetric conduit (pipe) of radius R but with a different constant. The average velocity is then half the maximum, and the pressure drop relation is:

$$dp/ds = -(8\mu V/R^2) \tag{8}$$

In Equation (6), for laminar flow in a wide rectangular channel, $\alpha = 1.54$, while for a pipe, $\alpha = 2.0$.

Turbulence

Fluid flows are generally turbulent, which involves random perturbations or fluctuations of the flow (velocity and pressure) characterized by an extensive hierarchy of scales or frequencies (Robertson 1963). Flow disturbances that are not random, but have some degree of periodicity, such as the oscillating vortex trail behind bodies, have been erroneously identified as turbulence. Only flows involving random perturbations without any order or periodicity are turbulent; the velocity in such a flow varies with time or locale of measurement (Figure 2).

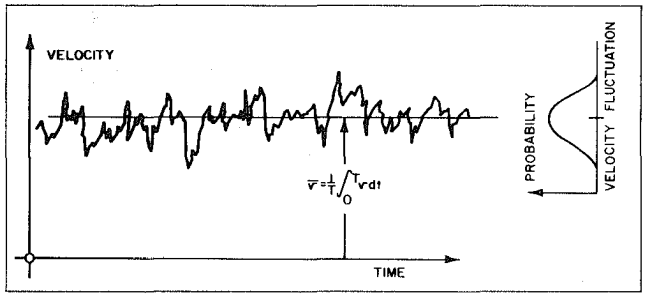

Fig. 2 Velocity Fluctuation at Point in Turbulent Flow

Turbulence can be quantified by statistical factors. Thus, the velocity most often used in velocity profiles is the temporal average velocity $\bar{v}$, and the strength of the turbulence is characterized by the root-mean-square of the instantaneous variation in velocity about this mean. The effects of turbulence cause the fluid to diffuse momentum, heat, and mass very rapidly across the flow.

The Reynolds number Re, a dimensionless quantity, gives the relative ratio of inertia to viscous forces.

$$\mathrm{Re} = VL/\nu$$

where L is a characteristic length and ν is the kinematic viscosity. In flow through round pipes and tubes, the characteristic length L is the diameter D. Generally, laminar flow in pipes can be expected if the Reynolds number, based on the pipe diameter, is less than 2000. Fully turbulent flow exists when $\mathrm{Re}_D > 10{,}000$. Between 2000 and 10,000, the flow is in a transition state and predictions are unreliable. In other geometries, different Re criteria exist.

BASIC FLOW PROCESSES

Wall Friction

At the boundary of real fluid flow, the relative tangential velocity at the fluid surface is zero. Sometimes in turbulent flow studies, velocity at the wall may appear finite, implying a fluid slip at the wall. However, this is not the case; the difficulty is in velocity measurement (Goldstein 1938). Zero wall velocity leads to a high shear stress near the wall boundary and a slowing down of adjacent fluid layers. A velocity profile develops near a wall, with the velocity increasing from zero at the wall to an exterior value within a finite lateral distance.

Laminar and turbulent flow differ significantly in their velocity profiles. Turbulent flow profiles are flat compared with more pointed laminar profiles (Figure 3). Near the wall, velocities of the turbulent profile must drop to zero more rapidly than those of the laminar profile, so the shear stress and friction are much greater in the turbulent flow case. Fully developed conduit flow may be characterized by the *pipe factor*, the ratio of average to maximum (centerline) velocity. Viscous velocity profiles result in pipe factors of 0.667 and 0.50 for wide rectangular and axisymmetric conduits. Figure 4 indicates much higher values for rectangular and circular conduits for turbulent flow. Due to the flat velocity profiles, the kinetic energy factor α for Equation (6) ranges from 1.01 to 1.10 in fully developed turbulent pipe flow.

Boundary-Layer Occurrence

In most flows, the friction of a bounding wall on the fluid flow is evidenced by a boundary layer. For flow around bodies, this layer (quite thin relative to distances in the flow direction) encompasses all viscous or turbulent actions, causing the velocity in it to vary rapidly from zero at the wall to that of the outer flow at its edge. Boundary layers are generally laminar near the start of their formation but may become turbulent downstream of the transition

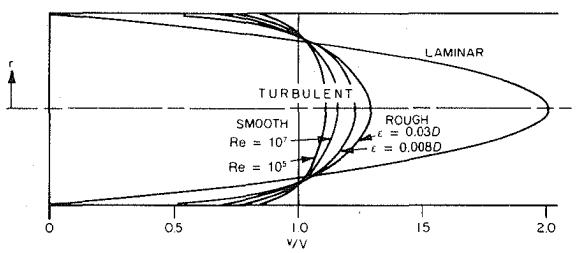

Fig. 3 Velocity Profiles of Flow in Pipes

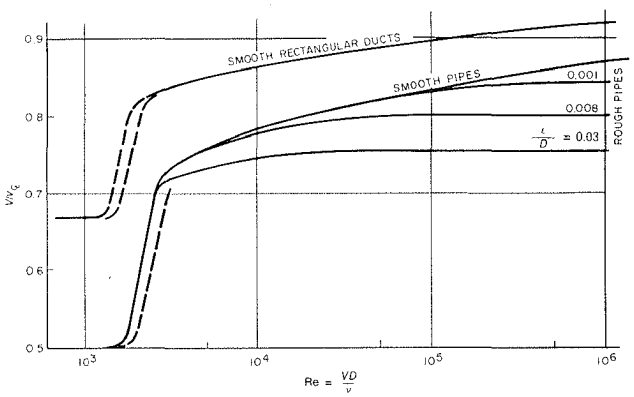

Fig. 4 Pipe Factor for Flow in Conduits

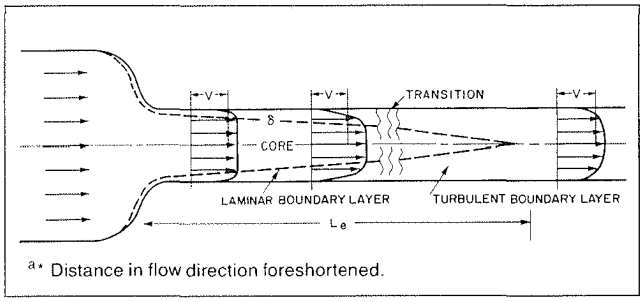

Fig. 5 Flow in Conduit Entrance Region[a]

point (Figure 5). For conduit flows, spacing between adjacent walls is generally small compared with distances in the flow direction. As a result, layers from the walls meet at the centerline to fill the conduit.

A significant boundary-layer occurrence is in a pipeline or conduit following a well-rounded entrance (Figure 5). Layers grow from the walls until they meet at the center of the pipe. Near the start of the straight conduit, the layer is very thin (and laminar in all probability), so the uniform velocity core outside has a velocity only slightly greater than the average velocity. As the layer grows in thickness, the slower velocity near the wall requires a velocity increase in the uniform core to satisfy continuity. As the flow proceeds, the wall layers grow (and the centerline velocity increases) until they join, after an entrance length L_e. Application of the Bernoulli relation of Equation (5) to the core flow indicates a decrease in pressure along the layer. Ross (1956) shows that although the entrance length L_e is many diameters, the length in which the pressure drop and head loss rates significantly exceed those for fully developed flow is on the order of 10 diameters for turbulent flow in smooth pipes.

In more general boundary-layer flows, as with wall layer development in a diffuser or for the layer developing along the surface of a strut or turning vane, pressure gradient effects can be severe and even lead to separation. The development of a layer in an adverse-pressure gradient situation (velocity v_1 at edge $y = \delta$ of layer decreasing in flow direction) with separation is shown in Figure 6. Downstream from the separation point, fluid backflows near the wall. Separation is due to frictional velocity (thus local kinetic energy) reduction near the wall. Flow near the wall no longer has energy to move into the higher pressure imposed by decrease in v_1 at the edge of the layer. The locale of this separation is difficult to predict, especially for the turbulent boundary layer. Analyses verify the experimental observation that a turbulent boundary layer is less subject to separation than a laminar one because of its greater kinetic energy.

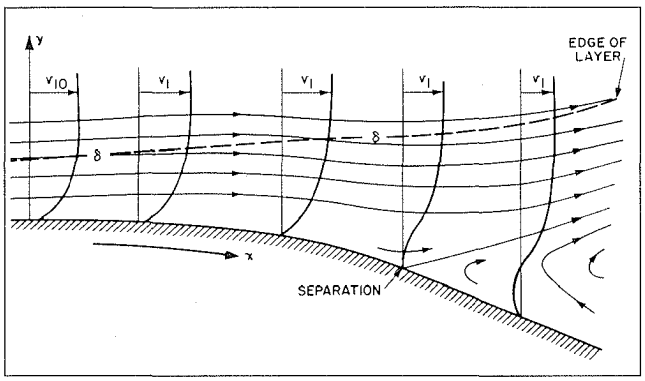

Fig. 6 Boundary Layer Flow to Separation

Flow Patterns with Separation

In technical applications, flow with separation is common and often accepted if it is too expensive to avoid. Flow separation may be geometric or dynamic. Dynamic separation is shown in Figure 6. Geometric separation (Figures 7 and 8) results when a fluid stream passes over a very sharp corner, as with an orifice; the fluid generally leaves the corner irrespective of how much its velocity has been reduced by friction.

For geometric separation in orifice flow (Figure 7), the outer streamlines separate from the sharp corners and because of fluid inertia, contract to a section smaller than the orifice opening, the *vena contracta*, with a limiting area of about six-tenths of the orifice opening. After the vena contracta, the fluid stream expands

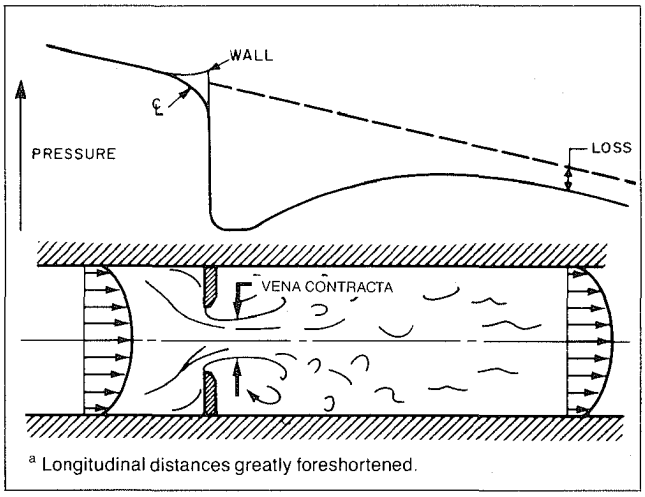

Fig. 7 Geometric Separation, Flow Development, and Loss in Flow through Orifice[a]

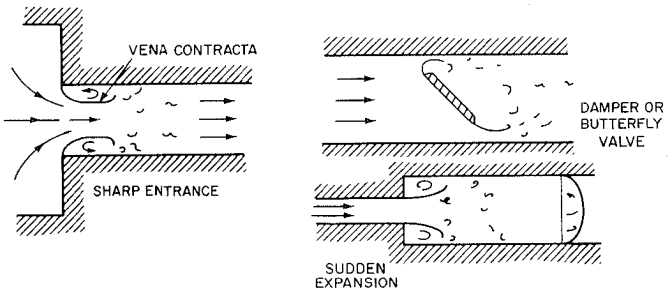

Fig. 8 Examples of Geometric Separation Encountered in Flows in Conduits

rather slowly through turbulent or laminar interaction with the fluid along its sides. Outside the jet, fluid velocity is small compared with that in the jet and is very disturbed. Strong turbulence vorticity helps spread out the jet, increases the losses, and brings velocity distribution back to a more uniform profile. Finally, at a considerable distance downstream, the velocity profile returns to the fully developed flow of Figure 2.

Other geometric separations (Figure 8) occur at a sharp entrance to a conduit, at an inclined plate or damper in a conduit, and at a sudden expansion. For these, a vena contracta can be identified; for sudden expansion, its area is that of the upstream contraction. Ideal fluid theory, using free streamlines, provides insight and predicts contraction coefficients for valves, orifices, and vanes (Robertson 1965). These geometric flow separations are large loss-producing devices. To expand a flow efficiently or to have an entrance with minimum losses, the device should be designed with gradual contours, a diffuser, or a rounded entrance.

Flow devices with gradual contours are subject to separation that is more difficult to predict, since it involves the dynamics of boundary layer growth under an adverse pressure gradient rather than flow over a sharp corner. In a diffuser, used to reduce the loss in expansion, it is possible to expand the fluid some distance at a gentle angle without difficulty (particularly if the boundary layer is turbulent). Eventually, separation may occur (Figure 9), which is frequently asymmetrical because of irregularities. Downstream flow involves flow reversal (backflow) and excess losses exist. Such separation is termed *stall* (Kline 1959). Larger area expansions may use splitters that divide the diffuser into smaller divisions less likely to have separations (Moore and Kline 1958). Another technique for controlling separation is to bleed some low velocity fluid near the wall (Furuya *et al.* 1976). Alternatively, Heskested (1965, 1970) shows that suction at the corner of a sudden expansion has a strong positive effect on geometric separation.

Drag Forces on Bodies or Struts

Bodies in moving fluid streams are subjected to appreciable fluid forces or drag. Conventionally expressed in coefficient form, drag forces on bodies can be expressed as:

$$D = C_D(\rho/2g)V^2 A \tag{9}$$

where A is the projected (normal to flow) area of the body. The drag coefficient C_D depends on the body's shape and angularity and the Reynolds number of the relative flow in terms of the body's characteristic dimension.

For Reynolds numbers of 10^3 to above 10^5, the C_D of most bodies is constant due to flow separation, but above 10^5, the C_D of rounded bodies suddenly drops as the surface boundary layer undergoes transition to turbulence. Typical C_D values are given in Table 1; Hoerner (1965) gives expanded values.

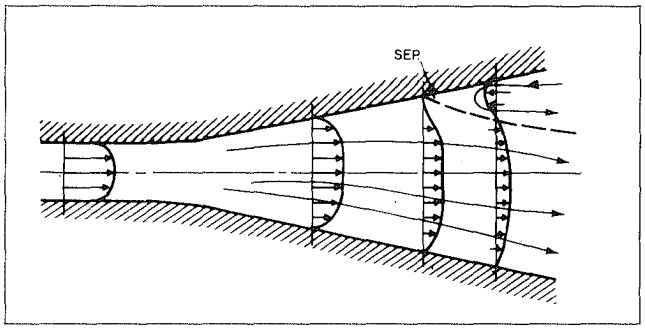

Fig. 9 Separation in Flow in Diffuser

Table 1 Drag Coefficients

Body Shape	$10^3 < Re < 2 \times 10^5$	$Re > 3 \times 10^5$
Sphere	0.36 to 0.47	~0.1
Disc	1.12	1.12
Streamlined strut	0.1 to 0.3	< 0.1
Circular cylinder	1.0 to 1.1	0.35
Elongated rectangular strut	1.0 to 1.2	1.0 to 1.2
Square strut	~2.0	~2.0

For a strut crossing a conduit, the contribution to the head loss of Equation (6) is:

$$H_L = C_D(A/A_c)(V^2/2g) \tag{10}$$

where A_c is the conduit cross-sectional area and A is the area of the strut facing the flow.

Cavitation

Liquid flow with gas- or vapor-filled pockets can occur if the absolute pressure is reduced to vapor pressure or less. In this case a cavity or series of cavities will form, since liquids are rarely pure enough to withstand any tensile stressing or pressures less than vapor pressure for any length of time (John and Haberman 1980, Knapp *et al.* 1970, Robertson and Wislicenus 1969). Robertson and Wislicenus (1969) indicate significant occurrences in various technical fields, chiefly in hydraulic equipment and turbomachines.

Initial evidence of cavitation is the collapse noise of many small bubbles that appear initially as they are carried by the flow into regions of higher pressure. The noise is not deleterious and serves as a warning of the occurrence. As flow velocity further increases or pressure decreases, severity of cavitation increases. More bubbles appear and may join to form large fixed cavities. The space they occupy becomes large enough to modify the flow pattern and alter performance of the flow device. Collapse of the cavities on or near solid boundaries becomes so frequent that the cumulative impact in time results in damage in the form of cavitational erosion of the surface or excessive vibration. As a result, pumps can lose efficiency or their parts may erode locally. Control valves may be noisy or seriously damaged by cavitation.

Cavitation in orifice and valve flow is indicated in Figure 10. With high upstream pressure and a low flow rate, no cavitation occurs. As pressure is reduced or flow rate increased, the minimum pressure in the flow (in the shear layer leaving the edge of the orifice) eventually approaches vapor pressure. Turbulence in this layer causes fluctuating pressures below the mean (as in vortex cores) and small bubble-like cavities. These are carried downstream into the region of pressure regain where they collapse, either in the fluid or on the wall (Figure 10A). As the pressure is reduced, more vapor- or gas-filled bubbles result and coalesce into larger ones. Eventually, a single large cavity results that collapses further downstream (Figure 10B). The region of wall damage is then as many as 20 diameters downstream from the valve or orifice plate.

Sensitivity of a device to cavitation occurrence is measured by the *cavitation index* or *number*, which is the ratio of available pressure above vapor pressure to the dynamic pressure of the reference flow, and can be expressed as:

$$\sigma = [p_o - p_v]/[(\rho/2g)V_o^2] \tag{11}$$

where the subscript o refers to appropriate reference conditions and p_v is the vapor pressure. Valve analyses use such an index in the specific form $(H_d - H_v)/(H - H_d)$ where u and d refer to upstream and downstream locales and H is the head (or pressure

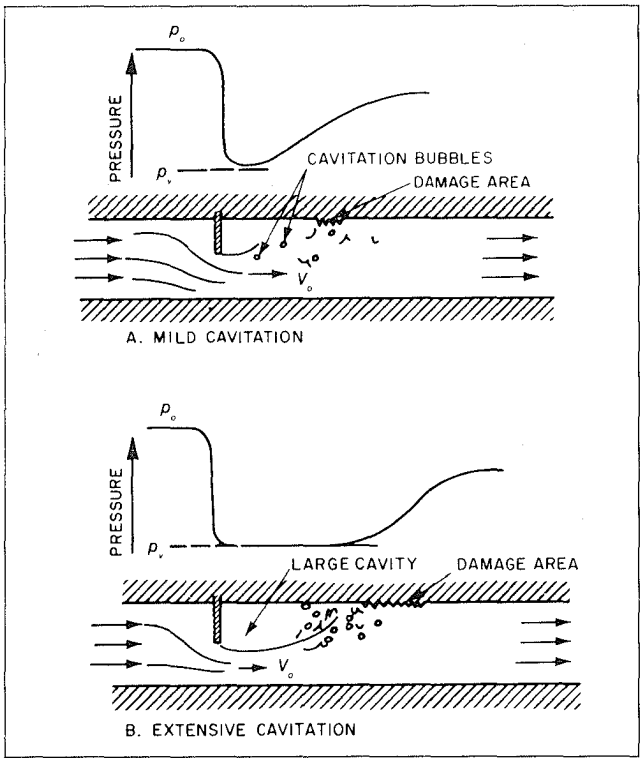

Fig. 10 Cavitation in Flows in Orifice or Valve

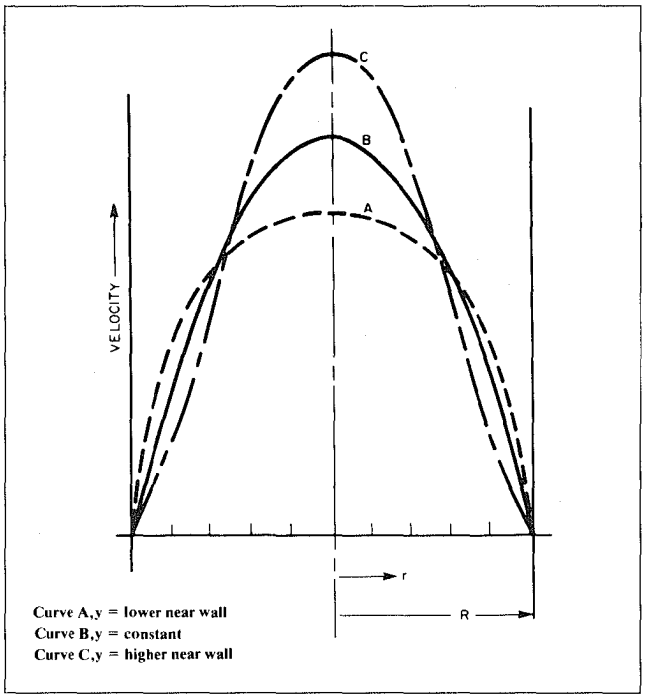

Fig. 11 Effect of Viscosity Variation on Velocity Profile of Laminar Flow in Pipe

divided by liquid specific weight). For the globe valve, the discharge coefficient changes at index values below 0.8 (Ball 1957). For the gate valve, the discharge coefficient begins to be reduced for index values below 1.5 at 10% opening and below 2.0 at 40% opening. With flow-metering devices such as orifices, venturis, and flow nozzles, there is little cavitation, since it occurs mostly downstream of the flow regions involved in establishing the metering action.

The detrimental effect of cavitation can be avoided by operating the liquid-flow device at high enough pressures. When this is not possible, the flow must be changed or the device must be built to withstand cavitation effects. Some materials or surface coatings are more resistant to cavitation erosion than others, but none is immune. Surface contours can be designed to delay the advent of cavitation.

Nonisothermal Effects

When appreciable temperature variations exist, the primary fluid properties (density and viscosity) are no longer constant, as usually assumed, but vary across or along the flow. The Bernoulli equation in the form of Equations (5a) through (5c) must be used, since volumetric flow is not constant. With gas flows, the thermodynamic process involved must be considered. In general, this is assessed in applying Equation (5a), written in the form:

$$\int \frac{dp}{\rho} + \frac{V^2}{2} + gz = \pi \tag{12}$$

Effects of viscosity variations also appear. With nonisothermal laminar flow, the parabolic velocity profile (Figure 3) is no longer valid. For gases, viscosity increases as the square root of absolute temperature, while for liquids, it decreases with increasing temperature. This results in opposite effects.

For fully developed pipe flow, the linear variation in shear stress from the wall value τ_w to zero at the centerline is independent of the temperature gradient. Since $y = R - r$, where R is the pipe radius $D/2$ and y is the distance from the wall, the relation for the change in velocity from Equation (1) becomes:

$$dv = \frac{\tau_w(R - y)dy}{R\mu} = -\frac{\tau_w}{R}\frac{1}{\mu} rdr \tag{13}$$

When the fluid has a lower viscosity near the wall than at the center (due to external heating of liquid or cooling of gas via heat transfer through the pipe wall), the velocity gradient is steeper near the wall and flatter near the center, so the profile is generally flattened. When liquid is cooled or gas is heated, the velocity profile becomes more pointed for laminar flow (Figure 11). Calculations are made for such flows of gases and liquid metals in pipes (Deissler 1951). Occurrences in turbulent flow are less apparent. If enough heating is applied to gaseous flows, the viscosity increase can cause reversion to laminar flow.

Buoyancy effects and gradual approach of the fluid temperature to equilibrium with that outside the pipe can cause considerable variation in the velocity profile along the conduit. Thus, Colborne and Drobitch (1966) found the pipe factor for upward vertical flow of hot air at a Reynolds number less than 2000 reduced to about 0.6 at 40 diameters from the entrance, then increased to about 0.8 at 210 diameters, and finally decreased to the isothermal value of 0.5 at the end of 320 diameters.

Compressibility

All fluids are compressible to some degree; their density depends on pressure. Steady liquid flow may ordinarily be treated as incompressible, and incompressible flow analysis is satisfactory for gases and vapors at velocities below about a few thousand feet per minute, except in long conduits.

For liquids in pipelines, if flow is suddenly stopped, a severe pressure surge or water hammer that travels along the pipe at the speed of sound in the liquid is produced. This pressure surge alternately compresses and decompresses the liquid. For steady gas flows in long conduits, a decrease in pressure along the conduit can reduce the specific mass (or density) of the gas signifi-

cantly enough to cause the velocity to increase. If the conduit is long enough, velocities approaching the speed of sound are possible at the discharge end, and the Mach number (ratio of the flow velocity to the speed of sound) must be considered.

Some compressible flows occur without heat gain or loss (adiabatically). If there is no friction (conversion of flow mechanical energy into internal energy), the process is reversible as well. Such a reversible adiabatic process is called isentropic, and follows the relationship:

$$p/\rho^k = \text{constant}$$

where k is the ratio of specific heats at constant pressure and volume with a value of 1.4 for air and diatomic gases.

The Bernoulli equation of steady flow, Equation (12), as an integral of the ideal-fluid equation of motion along a streamline, then becomes:

$$\int \frac{dp}{\rho} + \frac{V^2}{2} = \text{constant} \tag{14}$$

For a frictionless adiabatic process, the pressure term has the form:

$$\int_1^2 \frac{dp}{\rho} = \frac{k}{k-1}\left(\frac{p_2}{\rho_2} - \frac{p_1}{\rho_1}\right) \tag{15}$$

As in most compressible flow analyses, the elevation terms are insignificant and are dropped. Then, between stations 1 and 2 for the isentropic process:

$$\frac{p_1}{\rho_1}\left(\frac{k}{k-1}\right)\left[\left(\frac{p_2}{p_1}\right)^{(k-1)/k} - 1\right] + 0.5(V_2^2 - V_1^2) = 0 \tag{16}$$

Equation (16) replaces the Bernoulli equation for compressible flows and may be applied to the stagnation point at the front of a body. With this point as station 2 and the upstream reference flow ahead of the influence of the body as station 1, $V_2 = 0$ and:

$$p_s = p_2 = p_1\left[1 + \frac{k-1}{2}\frac{\rho_1 V_1^2}{k p_1}\right]^{k/(k-1)} \tag{17}$$

Since kp/ρ is the square of the acoustic velocity a and the Mach number $M = V/a$, the stagnation pressure relation becomes:

$$p_s = p_1\left[1 + \frac{k-1}{2}M_1^2\right]^{k/(k-1)} \tag{18}$$

For Mach numbers less than one:

$$p_s = p_1 + \frac{\rho_1}{2}V_1^2\left[1 + \frac{M_1}{4} + \frac{2-k}{24}M_1^4 + \ldots\right] \tag{19}$$

Equation (19) reduces to the incompressible flow result obtained from Equation (5a) when $M = 0$. Appreciable differences appear when the Mach number of the approaching flow exceeds 0.2. Thus a pitot tube in air is influenced by compressibility at velocities over 13,000 fpm.

Flows through a converging conduit, as in a flow nozzle, venturi, or orifice meter, also may be considered isentropic. Velocity at the upstream station 1 is negligible. From Equation (16), velocity at the downstream station is:

$$V_2 = \sqrt{[2k/(k-1)](p_1/\rho_1)[1 - (p_2/p_1)^{(k-1)/k}]} \tag{20}$$

The mass flow rate is:

$$w = V_2 A_2 \rho_2 = A_2\sqrt{[(2k/(k-1)](p_1\rho_1)[(p_2/p_1)^{2/k} - (p_2/p_1)^{(k+1)/k}]} \tag{21}$$

The corresponding incompressible flow relation is:

$$w_{in} = A_2\rho\sqrt{2\Delta p/\rho} = A_2\sqrt{2\rho(p_1 - p_2)} \tag{22}$$

The compressibility effect is often accounted for in the expansion factor Y:

$$w = Yw_{in} = A_2 Y\sqrt{2\rho(p_1 - p_2)} \tag{23}$$

Y is 1.00 for the incompressible case, while for air ($k = 1.4$), a value of 0.95 is reached with orifices at p_2/p_1 of 0.83 and with venturis at about 0.90, when these devices are of relatively small diameter ($D_2/D_1 = 0$ to 0.5). Further information on the compressibility correction factor Y is presented in the section of Chapter 13 that discusses orifice flowmeters.

As p_2/p_1 decreases, the flow rate increases, but more slowly than for the incompressible case because of the nearly linear decrease in Y. However, the downstream velocity reaches the local acoustic value and the discharge levels off at a value fixed by upstream pressure and density at the critical ratio:

$$\left.\frac{p_2}{p_1}\right|_c = \left(\frac{2}{k+1}\right)^{k/(k-1)} = 0.53 \text{ for air} \tag{24}$$

This *choking* (no increase in flow with lowering of downstream pressure) is used in some flow control devices to avoid flow dependence on downstream conditions.

FLOW ANALYSIS

Fluid flow analysis is used to correlate pressure changes with flow rates and nature of the conduit. For a given pipeline, either the pressure drop for a certain flow rate or the flow rate for a certain pressure difference between the ends of the conduit is needed. Flow analysis ultimately involves comparing a pump or blower to a conduit piping system for evaluating the expected flow rate.

Generalized Bernoulli Equation

Internal energy differences are generally small and usually the only significant effect of heat transfer is to change ρ. For gas or vapor flows, use the generalized Bernoulli equation in the pressure-over-density form of Equation (6a), allowing for the thermodynamic process in the pressure-density relation:

$$\int_1^2 \frac{dp}{\rho} + \alpha_1\frac{V_1^2}{2} + E_M = \alpha_2\frac{V_2^2}{2} + E_L \tag{25a}$$

where elevation changes are negligible. The pressure form of Equation (5b) is generally unacceptable when appreciable density variations occur, since the volumetric flow rate differs at the two stations. This is particularly serious in friction-loss evaluations where the density usually varies over considerable lengths of conduit (Benedict and Carlucci 1966). When the flow is essentially incompressible, Equation (25a) is satisfactory.

As an example, consider specifying the blower to produce an isothermal airflow of 400 cfm through a ducting system (Figure 12). Accounting for intake and fitting losses, the equivalent con-

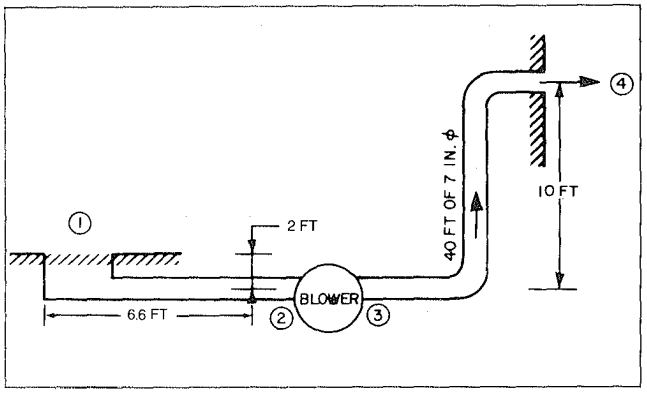

Fig. 12 Blower and Duct System

duit lengths are 60 and 165 ft and the flow is isothermal. The pressure head of the inlet (station 1) and that following the discharge (station 4) (where the velocity is zero) are the same. The frictional losses are evaluated as 24.5 ft of air between stations 1 and 2, and 237 ft between stations 3 and 4. The head form of the generalized Bernoulli relation is used in place of Equation (25a) (which could be used):

$$(p_1/\rho_1 g) + \alpha_1 (V_1^2/2g) + z_1 + H_M = (p_2/\rho_2 g) + \alpha_2 (V_2^2/2g) + z_2 + H_L \qquad (25b)$$

H_M is evaluated by applying this relation between any two points on opposite sides of the blower. Since conditions at stations 1 and 4 are fully known, they are used, and the location-specifying subscripts on the right side of Equation (25b) are changed to 4. Note that $p_1 = p_4 = p$, $\rho_1 = \rho_4 = \rho$, and $V_1 = V_4 = 0$; then:

$$(p/\rho g) + 0 + 2 + H_M = (p/\rho g) + 0 + 10 + (24.5 + 237)$$

so $H_M = 269.5$ ft of air. For standard air this corresponds to 3.88 in. of water.

The pressure (or head) difference measured across the blower (between stations 2 and 3), is often taken as the head H_M. The results are obtained by calculating the static pressure at stations 2 and 3. Applying Equation (25b) successively between stations 1 and 2 and between 3 and 4 gives:

$$(p_1/\rho g) + 0 + 2 + 0 = (p_2/\rho g) + 1.06 \times 3.54 + 0 + 24.5$$

$$(p_3/\rho g) + 1.03 \times 9.70 + 0 + 0 = (p_4/\rho g) + 0 + 10 + 237$$

Here, α just ahead of the blower has been taken as 1.06 and just after it as 1.03; the latter value is uncertain because of the possible uneven discharge from the blower. Static pressures p_1 and p_4 may be taken as zero gage; thus:

$$(p_2/\rho g) = -26.2 \text{ ft of air}$$

$$(p_3/\rho g) = 237 \text{ ft of air}$$

The static head across the blower, the difference between these two numbers, is 263.2 ft, which is *not* H_M. The apparent discrepancy results from ignoring the velocity heads at stations 2 and 3. Actually, H_M is the change in total head (pressure head plus true kinetic energy) across the machine; thus:

$$H_M = (p_3/\rho g) + \alpha_3(V_3^2/2g) - [(p_2/\rho g) + \alpha_2(V_2^2/2g)]$$
$$= 237.0 + 1.03 \times 9.7 - (-26.2 + 1.06 \times 3.54)$$
$$= 247 - (-22.5) = 269.5 \text{ ft of air}$$

The required blower head is the same, no matter how it is evaluated. It is the specific energy added to the system by the machine. Only when the conduit size and velocity profiles on both sides of the machine are the same is E_M or H_M simply found from $\Delta p = p_3 - p_2$.

Conduit Friction

The loss term E_L or H_L of Equation (6a) or (6b) accounts for friction caused by conduit-wall shearing stresses and losses from conduit-section changes. H_L is the loss of energy (ft-lb_f) per lb_m of flowing fluid.

In real fluid flow, a frictional shear occurs at bounding walls, gradually influencing the flow further away from the boundary. A lateral velocity profile is produced and flow energy is converted into heat (fluid internal energy), generally unrecoverable (a loss). This loss in fully developed conduit flow is evaluated through the Darcy-Weisbach relation:

$$(H_L)_f = f\,(L/D)(V^2/2g) \qquad (26)$$

where L is the length of conduit of diameter D and f is the *friction factor.* Sometimes a numerically different relation is used with the *Fanning friction factor* (one-quarter of f). The value of f is nearly constant for turbulent flow, varying only from about 0.01 to 0.05.

For fully developed laminar-viscous flow in a pipe, the loss is evaluated from Equation (8) as follows:

$$H_L = L\,\frac{8\mu V/\rho}{R^2 g} = \frac{32 L \nu V}{D^2 g} = \frac{64}{(VD/\nu)}\,\frac{L}{D}\,\frac{V^2}{2g}$$

so that:

$$f = 64/\text{Re} \quad \text{where} \quad \text{Re} = (VD/\nu) \qquad (27)$$

Thus with laminar flow, the friction factor varies inversely with the Reynolds number.

With turbulent flow, friction loss depends not only on flow conditions, as characterized by the Reynolds number, but also on the nature of the conduit wall surface. With smooth conduit walls, empirical correlations give:

$$f = (0.3164/\text{Re}^{0.25}) \qquad \text{for Re up to } 10^5 \qquad (28a)$$

$$= 0.0032 + \frac{0.221}{\text{Re}^{0.237}} \qquad \text{for } 10^5 < \text{Re} < 3 \times 10^6 \qquad (28b)$$

Generally, f also depends on the wall roughness ϵ. The mode of variation is complex and best expressed in chart form (Moody 1944) (Figure 13). Inspection indicates that, for high Reynolds numbers and relative roughness, the friction factor becomes independent of the Reynolds number in a *fully-rough flow regime.* Then:

$$f^{-0.5} = 1.14 + 2 \log (D/\epsilon) \qquad (29a)$$

Values of f between the values for smooth tubes and those for the fully-rough regime are represented by Colebrook's natural roughness function:

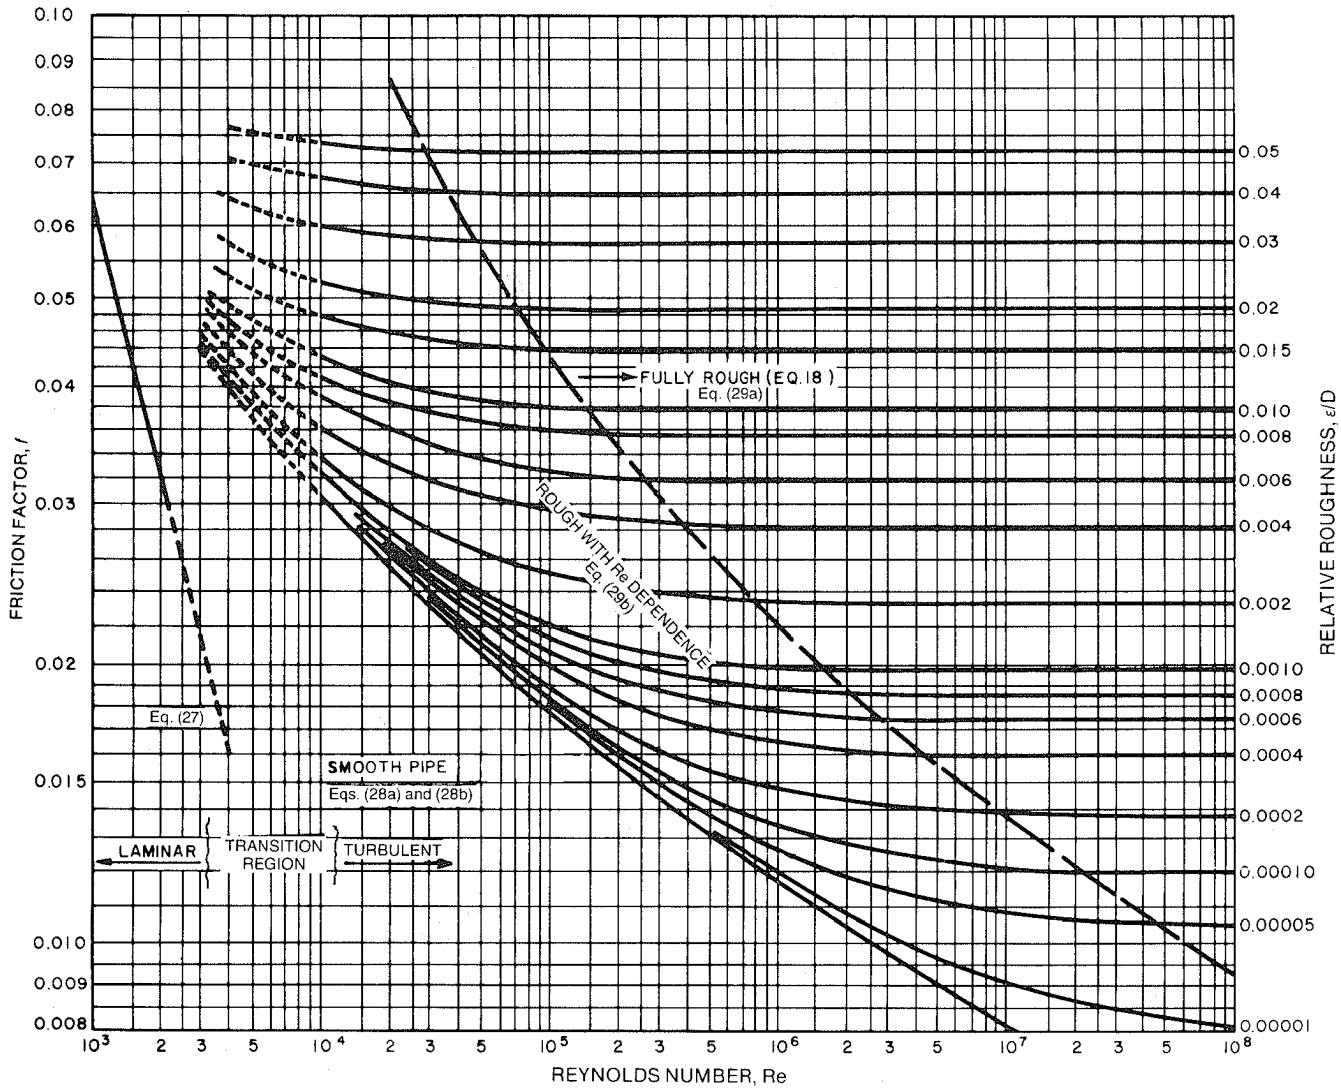

Fig. 13 Relation between Friction Factor and Reynolds Number
(Moody 1944)

$$f^{-0.5} = 1.14 + 2\log(D/\epsilon) - 2\log\left[1 + \frac{9.3}{\mathrm{Re}(\epsilon/D)f^{0.5}}\right] \quad (29b)$$

A transition region appears in Figure 13 for Reynolds numbers between 2000 and 10,000. Below this critical condition, for smooth walls, Equation (27) is used to determine f; above the critical condition, Equation (28b) is used. For rough walls, Figure 13 or Equation (29b) must be used to assess the friction factor in turbulent flow. To do this, the roughness height ϵ, which may increase with conduit use or aging, must be evaluated from the conduit surface (Table 2).

While the preceding discussion has focused on circular pipes or ducts, air ducts are often rectangular in cross section. The equivalent circular conduit corresponding to the noncircular conduit must be found before Figure 13 or Equations (28) or (29) can be entered. Based on turbulent flow concepts, the equivalent diameter is determined by:

$$D_{eq} = (4A/P_w) \quad (30)$$

where A is the flow area and P_w the wetted perimeter of the cross section. For turbulent flow, D_{eq} is substituted for D in Equation (24) and the Reynolds number definition. Noncircular duct friction can be evaluated to within 5% for all except very extreme cross sections. A more refined method for finding the equivalent circular duct diameter is given in Chapter 32. With laminar flow, the loss predictions may be off by a factor as large as two.

Table 2 Effective Roughness of Conduit Surfaces

Material	ϵ, ft
Commercially smooth brass, lead, copper, or plastic pipe	0.000005
Steel and wrought iron	0.00015
Galvanized iron or steel	0.0005
Cast iron	0.00085

Section Change Effects and Losses

Valve and section changes (contractions, expansions and diffusers, elbows or bends, tees), as well as entrances, distort the fully developed velocity profiles (Figure 3) and introduce extra flow losses (dissipated as heat) into pipelines or duct systems. Valves produce such extra losses to control flow rate. In contractions and expansions, flow separation as shown in Figures 8 and 9 causes the extra loss. The loss at rounded entrances develops as

the flow accelerates to higher velocities. The resulting higher velocity near the wall leads to wall shear stresses greater than those of fully developed flow (Figure 5). In flow around bends, the velocity increases along the inner wall near the start of the bend. This increased velocity creates a secondary motion, which is a double helical vortex pattern of flow downstream from the bend. In all these devices, the disturbance produced locally is converted into turbulence and appears as a loss in the downstream region.

The return of disturbed flow to a fully developed velocity profile is quite slow. Ito (1962) showed that the secondary motion following a bend takes up to 100 diameters of conduit to die out, but the pressure gradient settles out after 50 diameters.

With laminar flow following a rounded entrance (Figure 8), the entrance length depends on the Reynolds number:

$$(L_e/D) \cong 0.06\ \mathrm{Re} \tag{31}$$

At Re = 2000, a length of 120 diameters is needed to establish the parabolic profile. The pressure gradient reaches the developed value of Equation (26) much sooner. The extra head drop is 1.2 velocity heads; 1.0 velocity heads result from the change in profile from uniform to parabolic (since $\alpha = 2.0$) and the rest is due to excess friction. With turbulent flow, 80 to 100 diameters following the rounded entrance are needed for the velocity profile to become fully developed, but the friction loss per unit length reaches a value close to that of the fully developed flow value more quickly. After six diameters, the loss rate at a Reynolds number of 10^5, is only 14% above that of fully developed flow in the same length, while at 10^7 it is only 10% higher (Robertson 1963). For a sharp entrance, the flow separation (Figure 8) causes a greater disturbance, but fully developed flow is achieved in about half the length required for a rounded entrance. With sudden expansion, the pressure change settles out in about eight times the diameter change $(D_2 - D_1)$, while the velocity profile takes at least a 50% greater distance to return to fully developed pipe flow (Lipstein 1962).

These disturbance effects are assumed compressed (in the flow direction) into a point, and the losses are treated as locally occurring. Such losses are related to the velocity head by:

$$\text{Loss of section} = K(V^2/2g) \tag{32}$$

Chapter 33 and the *Pipe Friction Manual* (HI 1961) have information for pipe applications. Chapter 32 gives information for airflow. The same type of fitting in pipes and ducts may give a different loss, since flow disturbances are controlled by the detailed geometry of the fitting. The elbow of a small pipe may be a threaded fitting that differs from a bend in a circular duct. For 90° screw-fitting elbows, K is about 0.8 (Ito 1962), whereas smooth flanged elbows have a K as low as 0.2 at the optimum curvature.

Table 3 gives a list of fitting loss coefficients. These values indicate the losses, but there is considerable variance. Not included are expansion flows, as from one conduit size to another or at exit into a room or reservoir. For such occurrences, the Borda loss prediction (from impulse-momentum considerations) is appropriate:

$$\text{Loss at expansion} = (V_1 - V_2)^2/2g = \left(1 - \frac{A_1}{A_2}\right)^2 \frac{V_1^2}{2g} \tag{33}$$

Such expansion loss is reduced by avoiding or delaying separation using a gradual diffuser (Figure 9). For a diffuser of about 7° total angle, the loss is minimal, about one-sixth that given by Equation (21). The diffuser loss for total angles above 45 to 60° exceeds that of the sudden expansion, depending somewhat on the diameter ratio of the expansion. Optimum design of diffusers involves many factors; excellent performance can be achieved in short diffusers with splitter vanes or suction. Turning vanes in miter bends produce the least disturbance and loss for elbows; with careful design, the loss coefficient can be reduced to as low as 0.1.

Table 3 Fitting Loss Coefficients of Turbulent Flow

Fitting	Geometry	$K = \frac{\Delta p/\rho g}{V^2/2g}$
Entrance	Sharp	0.50
	Well-rounded	0.05
Contraction	Sharp ($D_2/D_1 = 0.5$)	0.38
90° Elbow	Miter	1.3
	Short radius	0.90
	Long radius	0.60

For losses in smooth elbows, Ito (1962) found a Reynolds number effect (K slowly decreasing with Re) and the minimum loss at a bend curvature of 2.5 (bend radius to diameter ratio). At this optimum curvature, a 45° turn had 63%, and a 180° turn approximately 120%, of the loss of a 90° bend. The loss does not vary linearly with the turning angle because secondary motion occurs.

Use of coefficient K presumes its independence of the Reynolds number. Crane Co. (1976) found a variation with the Reynolds number similar to that of the friction factor; Kittridge and Rowley (1957) observed it only with laminar flow. Assuming that K varies with Re similarly to f, it is convenient to represent fitting losses as adding to the effective length of uniform conduit. The effective length of a fitting is then:

$$(L_{eff}/D) = (K/f_{ref}) \tag{34}$$

where f_{ref} is an appropriate reference value of the friction factor. Deissler (1951) uses 0.028, while the air duct values in Chapter 32 are based on an f_{ref} of about 0.02. For rough conduits, appreciable errors can occur if the relative roughness does not correspond to that used when f_{ref} was fixed. It is unlikely that the fitting losses involving separation are affected by pipe roughness. The effective length method for fitting loss evaluation is still useful.

When a conduit contains a number of section changes or fittings, the values of K are added to the fL/D friction loss, or the L_{eff}/D of the fittings are added to the conduit length L/D for evaluating the total loss H_L. This assumes that each fitting loss is fully developed and its disturbance fully smoothed out before the next section change. Such an assumption is frequently wrong, and the total loss can be overestimated. For elbow flows, the total loss of adjacent bends may be over- or underestimated. The secondary flow pattern following a radius elbow is such that when one elbow follows another, perhaps in a different plane, the secondary flow production of the second elbow may reinforce or partially cancel that of the first. Moving the second elbow a few diameters can reduce the total loss (from more than twice the amount) to less than the loss from one elbow. Screens or perforated plates can be used for smoothing velocity profiles (Wile 1947) and flow spreading. Their effectiveness and loss coefficients depend on their amount of open area (Baines and Peterson 1951).

Compressible Conduit Flow

When friction loss is included, as it must be except for a very short conduit, the incompressible flow analysis previously con-

sidered applies until the pressure drop exceeds about 10% of the initial pressure. The possibility of sonic velocities at the end of relatively long conduits limits the amount of pressure reduction achieved. For an inlet Mach number of 0.2, the discharge pressure can be reduced to about 0.2 of the initial pressure; for an inflow at $M = 0.5$, the discharge pressure cannot be less than about $0.45p_1$ in the adiabatic case and about $0.6p_1$ in isothermal flow.

Analysis of such conduit flow must treat density change, as evaluated from the continuity relation [Equation (2)], with the frictional occurrences evaluated from wall roughness and Reynolds number correlations of incompressible flow (Binder 1944). In evaluating valve and fitting losses, consider the reduction in K caused by compressibility (Benedict and Carlucci 1966). Although the analysis differs significantly, isothermal and adiabatic flows involve essentially the same pressure variation along the conduit, up to the limiting conditions.

Control Valve Characterization

Control valves are characterized by a discharge coefficient C_d. As long as the Reynolds number is above 250, the orifice equation holds for liquids.

$$Q = C_d A_o \sqrt{2\Delta P/\rho} \tag{35}$$

where A_o is the area of orifice opening.

The discharge coefficient is about 0.63 for sharp-edged configurations and 0.8 to 0.9 for chamfered or rounded configurations. For gas flows at pressure ratios below the choking critical [Equation (24)], the flow is:

$$w = C_d A_o C_1 \times (P_u/\sqrt{T_u})(\sqrt{P_d/P_u})\sqrt{1-(P_d/P_u)^{(k-1)/k}} \tag{36}$$

where

w = mass rate of flow
A_o = area of orifice
$C_1 = g\sqrt{2k/R(k-1)}$
k = ratio of specific heat at constant pressure and volume
R = gas content
P = absolute pressure
T = absolute temperature

Subscripts u and d refer to upstream and downstream positions.

Incompressible Flow in Systems

Flow devices must be evaluated in terms of their interaction with other elements of the system, *e.g.*, the action of valves in modifying flow rate and in matching the flow-producing device (pump or blower) with system loss. Analysis is via the general Bernoulli equation and the loss evaluations noted previously.

A valve regulates or stops the flow of fluid by throttling. The change in flow is not proportional to the change in area of the valve opening. Figures 14 and 15 indicate the nonlinear action of valves in controlling flow. A gate valve opening controls the flow in a pipeline discharging water from a tank (Figure 14). The K values are those of Table 3; f is 0.027. The degree of control also depends on the conduit L/D. For a relatively long conduit, the valve must be nearly closed before its high K value becomes a significant portion of the loss. Figure 15 shows a control damper (essentially a butterfly valve) in a duct discharging air from a plenum held at constant pressure. With a long duct, the damper does not affect the flow rate until it is about one-quarter closed. Duct length has little effect when the damper is more than half closed. The damper closes the duct totally at the 90° position ($K = \infty$).

Flow in a system (pump or blower and conduit with fittings) involves interaction between the characteristics of the flow-producing device (pump or blower) and the loss characteristics of the pipeline or duct system. Often the devices are centrifugal,

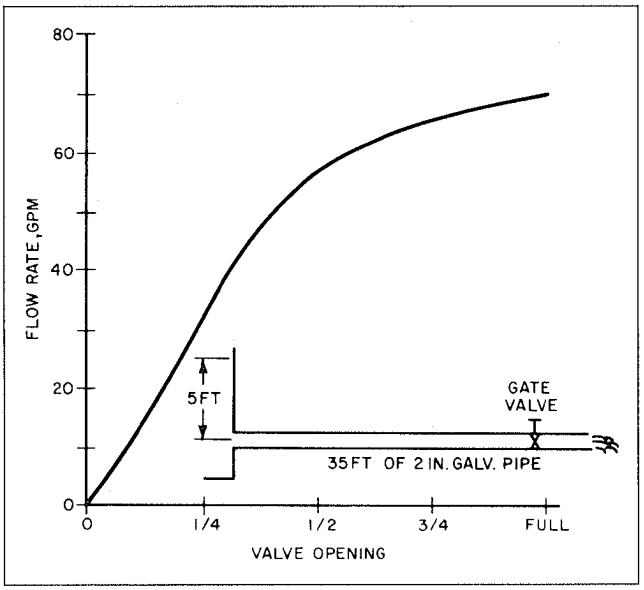

Fig. 14 Valve Action in Pipeline

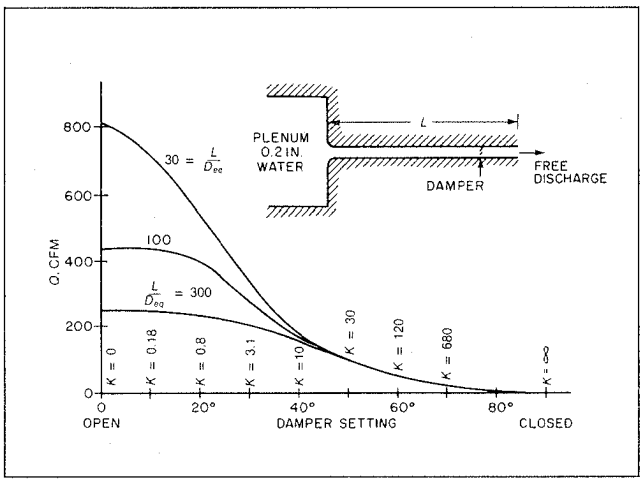

Fig. 15 Effect of Duct Length on Damper Action

in which case the head produced decreases as flow rate increases, except for the lowest flow rates. System head required to overcome losses increases roughly as the square of the flow rate. The flow rate of a given system is that for which the two heads match, where the two curves of head versus flow rate cross (point 1 in Figure 16). When a control valve (or damper) is partially closed, it increases the losses and reduces the flow (point 2 in Figure 16). For cases of constant head, the flow decrease due to valving is not as great as that indicated in Figures 14 and 15.

Flow Measurement

The general principles noted (continuity and Bernoulli equations) are basic to most fluid-metering devices. Chapter 13 has further details.

The pressure difference between the stagnation point (total pressure) and that in the ambient fluid stream (static pressure) is used to give a point velocity measurement. Flow rate in a conduit is measured with a pitot device by placing it at various locations in the cross section and spatially integrating the velocity profile found. A single point measurement may be used for approximate flow rate evaluation. When the flow is fully developed, the pipe-factor information of Figure 4 can be used to estimate the flow

rate from a centerline measurement. Measurements can be made in one of two modes. With the pitot-static tube, the ambient (static) pressure is found from pressure taps along the side of the forward-facing portion of the tube. When this portion is not long and slender, static pressure indication will be low and velocity indication high; as a result, a tube coefficient less than unity must be employed. For parallel conduit flow, wall piezometers (taps) may take the ambient pressure, and the pitot tube indicates the impact (total pressure).

The venturi meter, flow nozzle, and orifice meter are flow rate metering devices based on the pressure change associated with relatively sudden changes in conduit section area (Figure 17). The elbow meter is another differential pressure flow meter (also shown in Figure 17). The flow nozzle is similar to the venturi in action, but does not have the downstream diffuser. For all these, flow rate is proportional to the square root of the pressure difference resulting from fluid flow. With the area change devices (venturi, flow nozzle, and orifice meter), a theoretical flow rate relation is found by applying the Bernoulli and continuity equations [Equations (6) and (2)] between stations 1 and 2, so that:

$$Q_{theor} = (\pi d^2/4)\sqrt{2g\Delta h/(1 - \beta^4)} \quad (37)$$

where $\Delta h = h_1 - h_2 = \Delta p/\rho g$ (h is static pressure head), and $\beta = d/D$, the ratio of throat (or orifice) diameter to conduit diameter. The actual flow rate through the device can differ because the approach flow kinetic energy factor α deviates from unity and because of small losses. More significantly, the jet contraction of orifice flow is neglected in deriving Equation (37), to the extent that it can reduce the effective flow area by a factor of 0.6. The effect of all these factors is lumped into the discharge coefficient C_d, so that:

$$Q = C_d Q_{theor} = C_d (\pi d^2/4)\sqrt{2g\Delta h/(1 - \beta^4)} \quad (38)$$

Sometimes an alternate coefficient is used in the form

$$C_d/\sqrt{1 - \beta^4}$$

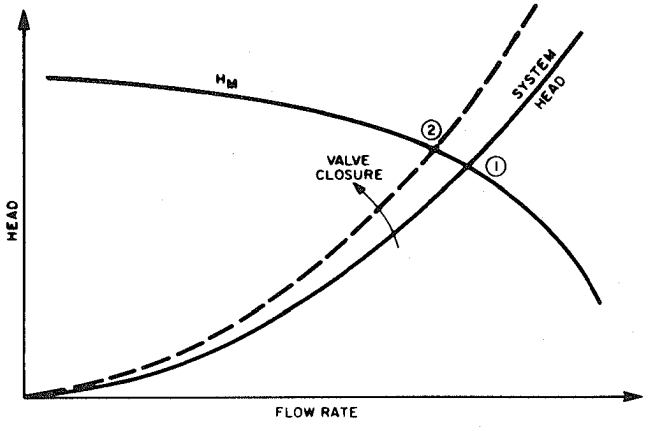

Fig. 16 Matching of Pump or Blower to System Characteristics

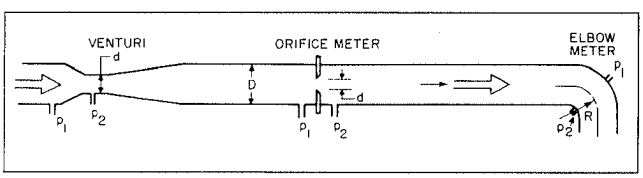

Fig. 17 Differential Head Flow Meters

For compressible fluid metering, the expansion factor Y as described by Equation (23) must be included, and the mass flow rate calculated:

$$w = C_d Y\rho Q_{theor} = C_d Y(\pi d^2/4)\sqrt{2\rho\Delta p/(1 - \beta^4)} \quad (39)$$

Values of Y depend primarily on the pressure ratio p_2/p_1, but also on the metering device and k value of the particular gas.

The general mode of variation in C_d for orifices and venturis is indicated in Figure 18 as a function of Reynolds number and, to a lesser extent, diameter ratio β. For Reynolds numbers less than 10, the coefficient varies as $\sqrt{\text{Re}}$.

The elbow meter (Murdock *et al.* 1964) employs the pressure difference between inside and outside the bend as the metering signal. A momentum analysis gives the flow rate as:

$$Q = (\pi D^2/4)\sqrt{R/2D}\ \sqrt{(2g\Delta h)} \quad (40)$$

where R is the radius of curvature of the bend. Again, a discharge coefficient C_d is needed; as in Figure 18, this drops off for the lower Reynolds numbers (below 10^5). These devices are calibrated in pipes with fully developed velocity profiles, so they must be located far enough downstream of sections that modify the approach velocity.

Unsteady Flow

Conduit flows are not always steady. In a compressible fluid, the acoustic velocity is usually high and conduit length is rather short, so the time of signal travel is negligibly small. Even in the incompressible approximation, system response is not instantaneous. If a pressure difference Δp is applied between the conduit ends, the fluid mass must be accelerated and wall friction overcome, so a finite time passes before the steady flow rate corresponding to the pressure drop is achieved.

The time it takes for an incompressible fluid in a horizontal constant-area conduit of length L to achieve steady flow may be estimated by using the unsteady flow equation of motion with wall friction effects included. On the quasi-steady assumption, friction is given by Equation (26); also by continuity, V is constant along the conduit. The occurrences are characterized by the relation:

$$(dV/d\theta) + (dp/\rho ds) + (fV^2/2D) = 0 \quad (41)$$

where θ is time and s is distance in the flow direction.

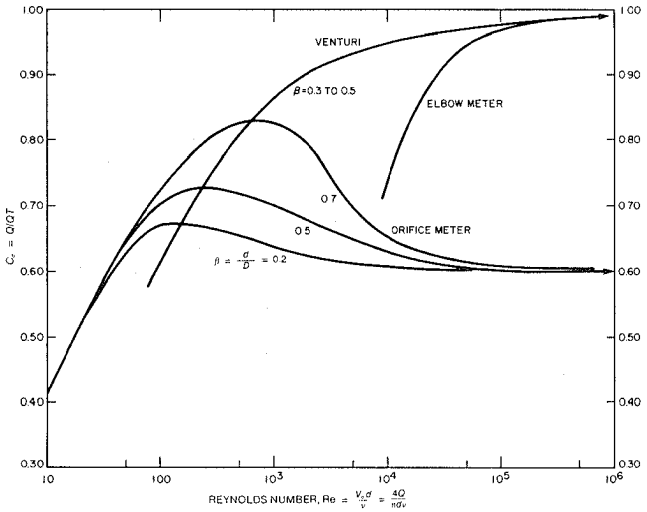

Fig. 18 Flow Meter Coefficients

Since a certain Δp is applied over the conduit length L:

$$(dV/d\theta) = (\Delta p/\rho L) - (fV^2/2D) \quad (42)$$

For laminar flow, f is given by Equation (27), and then:

$$(dV/d\theta) = (\Delta p/\rho L) - (32\mu V/\rho D^2) = A - BV \quad (43)$$

This is rearranged and integrated to yield the time to reach a certain velocity:

$$\theta = \int d\theta = \int \frac{dV}{(A - BV)} = -\frac{1}{B} \ln (A - BV) \quad (44)$$

and

$$V = (\Delta p/L)(D^2/32\mu)\,[1 - \exp(-32\nu\theta/D)] \quad (45a)$$

For large times ($\theta \rightarrow \infty$), this indicates steady velocity as:

$$V_\infty = (\Delta p/L)(D^2/32\mu) = (\Delta p/L)(RZ^2/8\mu) \quad (45b)$$

as by Equation (8). Then:

$$V = V_\infty\,[1 - \exp(-f_\infty V_\infty \theta/2D)] \quad (46)$$

The general nature of velocity development for starting-up flow is derived by more complex techniques; however, the temporal variation is as given above. For shutdown flow (steady flow with $\Delta p = 0$ at $\theta > 0$), the flow decays exponentially as $e^{-\theta}$.

Turbulent flow analysis of Equation (41) also must be based on the quasi-steady approximation, with less justification. Daily *et al.* (1956) indicate frictional resistance to be slightly greater than the steady-state result for accelerating flows, but appreciably less for decelerating ones. If the friction factor is approximated as constant:

$$dV/d\theta = (\Delta p/\rho L) - f(V^2/2D) = A - BV^2$$

and, for the accelerating flow:

$$\theta = \frac{1}{\sqrt{AB}} \tanh^{-1} (V\sqrt{B/A})$$

or:

$$V = \sqrt{A/B} \tanh (\theta\sqrt{AB})$$

Since the hyperbolic tangent is zero when the independent variable is zero and unity when the variable is infinity, the initial ($V = 0$ at $\theta = 0$) and final conditions are verified. Thus, for large times ($\theta \rightarrow \infty$):

$$V_\infty = \sqrt{A/B} = \sqrt{(\Delta p/\rho L)(2D/f)}$$

which is in accord with Equation (26) when f is constant (the flow regime is the fully rough one of Figure 13). The temporal velocity variation then is:

$$V = V_\infty \tanh [(f V_\infty/2D)/\theta] \quad (47)$$

The turbulent velocity start-up result is compared with the laminar one in Figure 19, where initially it appears somewhat faster but of the same general form, increasing rapidly at the start but reaching V_∞ asymptotically.

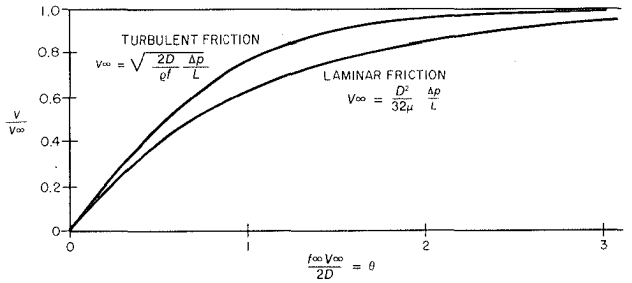

Fig. 19 Temporal Increase in Velocity Following Sudden Application of Pressure

NOISE FROM FLUID FLOW

Noise in flowing fluids results from unsteady flow fields and can be at discreet frequencies or broadly distributed over the audible range. With liquid flow, cavitation results in noise through the collapse of vapor bubbles. The noise in pumps or fittings (such as valves) can be a rattling or sharp hissing sound. It is easily eliminated by raising system pressure. With severe cavitation, the resulting unsteady flow can produce indirect noise from induced vibration of adjacent parts.

The disturbed laminar flow behind cylinders can be an oscillating motion. The shedding frequency of these vortexes is characterized by a Strouhal number St = fd/V of about 0.21 for the circular cylinder of diameter d, over a considerable range in Reynolds numbers. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* has further details. This oscillating flow can be a powerful noise source, particularly when f is close to the natural frequency of the cylinder or some nearby structural member, so that resonance occurs. With cylinders of another shape, as impeller blades of a pump or blower, the characterizing Strouhal number involves the trailing edge thickness of the member. The strength of the vortex wake, with its resulting vibrations and noise potential, can be reduced by breaking up the flow with downstream splitter plates or boundary-layer trip devices (wires) on the cylinder surface.

Noise produced in pipes and ducts, especially from valves and fittings, is associated with the loss through such elements. The sound pressure of noise in water pipe flow increases linearly with the head loss; the broad-band noise increases but only in the lower frequency range. Fitting-produced noise levels also increase with their loss (even without cavitation) and significantly exceed that of the pipe flow. The relation between noise and loss is not surprising since they both involve excessive flow perturbations. A valve's pressure-flow characteristics and structural elasticity may be such that for some operating point it will oscillate, perhaps in resonance with part of the piping system, to produce excessive noise. A change in the operating point conditions or details of the valve geometry can result in significant noise reduction.

Pumps and blowers are strong potential noise sources. Turbomachinery noise is associated with blade-flow occurrences. Broad-band noise appears from vortex and turbulence interaction with walls and is primarily a function of the operating point of the machine. For blowers, it has a minimum at the peak efficiency point (Groff *et al.* 1967). Narrow-band noise also appears at the blade-crossing frequency and its harmonics. Such noise can be very annoying because it stands out from the background. To reduce this noise, increase clearances between impeller and housing, and space the impeller blades unevenly around the circumference.

CHAPTER 3

HEAT TRANSFER

Heat Transfer Processes 3.1
Steady-State Conduction 3.1
Overall Heat Transfer 3.2
Transient Heat Flow 3.4
Thermal Radiation 3.6
Natural Convection 3.11
Forced Convection 3.13
Extended Surface 3.17
Symbols 3.22

HEAT is energy in transition caused by a temperature difference. The process and study thereof is called heat transfer. The thermal energy is transferred from one region to another by three modes: conduction, convection, and radiation. Heat transfer is among the transport phenomena that include mass transfer (see Chapter 5), momentum transfer or fluid friction (see Chapter 2), and electrical conduction. Transport phenomena have similar rate equations, and flux is proportional to a potential difference. In heat transfer by conduction and convection, the potential difference is the temperature difference. Heat, mass, and momentum transfer are often considered together because of their similarities and interrelationship in many common physical processes.

This chapter presents the elementary principles of single-phase heat transfer with emphasis on heating, refrigerating, and air conditioning. Boiling and condensation are discussed in Chapter 4. More specific information on heat transfer to or from buildings or refrigerated spaces can be found in Chapters 22 through 28. Physical properties of substances can be found in Chapters 16, 20, 22, 30, and 36. Heat transfer equipment, including evaporators, condensers, heating and cooling coils, furnaces, and radiators, are covered in the 1992 ASHRAE *Handbook—Systems and Equipment*. For further information on heat transfer, see the bibliography.

HEAT TRANSFER PROCESSES

Thermal conduction is the mechanism of heat transfer whereby energy is transported between parts of a continuum by the transfer of kinetic energy between particles or groups of particles at the atomic level. In gases, conduction is a result of elastic collision of molecules; in liquids and electrically nonconducting solids, it is believed to be caused by longitudinal oscillations of the lattice structure. Thermal conduction in metals occurs like electrical conduction, through motions of free electrons. Thermal energy transfer occurs in the direction of decreasing temperature, a consequence of the *second law of thermodynamics*. In solid opaque bodies, the significant heat transfer mechanism is thermal conduction, since no net material flows in the process. With flowing fluids, thermal conduction dominates in the region very close to a solid boundary where the flow is *laminar* and parallel to the surface, and where there is no eddy motion.

Thermal convection may involve energy transfer by eddy mixing and diffusion in addition to conduction (Burmeister 1983, Kays and Crawford 1980). Consider heat transfer to a fluid flowing inside a pipe. If the Reynolds number is large enough, three different flow regions exist. Immediately adjacent to the wall is a *laminar sublayer* where heat transfer occurs by thermal conduction; outside the laminar sublayer is a transition region called the *buffer layer*, where both eddy mixing and conduction effects are significant; beyond the buffer layer and extending to the center of the pipe is the *turbulent region*, where the dominant mechanism of transfer is eddy mixing.

In most equipment, the main body of fluid is in turbulent flow, and the laminar layer exists at the solid walls only. In cases of low-velocity flow in small tubes, or with viscous liquids such as oil (*i.e.*, at low Reynolds numbers), the entire flow may be laminar with no transition or eddy region.

When fluid currents are produced by external sources (for example, a blower or pump), the solid-to-fluid heat transfer is termed *forced convection*. If the fluid flow is generated internally by nonhomogeneous densities caused by temperature variation, the heat transfer is termed *free* or *natural convection*.

In conduction and convection, heat transfer takes place through matter. For *thermal radiation*, there is a change in energy form; from internal energy at the source to electromagnetic energy for transmission, then back to internal energy at the receiver. Whereas conduction and convection are affected primarily by temperature difference and somewhat by temperature level, the heat transferred by radiation increases rapidly as the temperature increases.

Although some generalized heat transfer equations have been mathematically derived from fundamentals, they are usually obtained from correlations of experimental data. Normally, the correlations employ certain dimensionless numbers from analyses such as dimensional analysis or analogy. Table 1 lists some important dimensionless numbers.

STEADY-STATE CONDUCTION

For steady-state heat conduction in one dimension, the Fourier equation applies:

$$q = -kA(dt/dx) \tag{1}$$

where

q = heat flow rate, Btu/h
k = thermal conductivity, Btu/h · ft · °F
A = cross-sectional area normal to flow, ft^2
dt/dx = temperature gradient, °F/ft

Equation (1) states that the heat flow rate q in the x direction is directly proportional to the temperature gradient dt/dx and the cross-sectional area A normal to the flow. The proportionality factor is the thermal conductivity k. The minus sign indicates that the heat flow is positive in the direction of decreasing temperature. Since conductivity values are sometimes given in other units, consistent units must be used.

Equation (1) may be integrated along a path of constant heat flow rate to obtain:

$$q = k(A_m/L_m)\Delta t = \Delta t/R \tag{2}$$

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Table 1 Dimensionless Numbers Commonly Used in Heat Transfer[a]

Name	Symbol	Value	Application
Nusselt number	Nu	hD/k or hL/k	Natural or forced convection, Boiling or condensing
Reynolds number	Re	GD/μ or $\rho VL/\mu$	Forced convection
Prandtl number	Pr	$\mu c_p/k$	Natural or forced convection, Boiling or condensing
Stanton number	St	h/Gc_p	Forced convection
Grashof number	Gr	$L^3\rho^2\beta g\Delta t/\mu^2$ or $L^3\rho^2 g\Delta t/T\mu^2$	Natural convection (for ideal gases)
Fourier number	Fo	$\alpha\tau/L^2$	Unsteady state conduction
Peclet number	Pe	GDc_p/k or Re Pr	Forced convection (small Pr)
Graetz number	Gz	GD^2c_p/kL or Re Pr D/L	Laminar convection

[a]A complete list of symbols appears at the end of this chapter.

where

A_m = mean cross-sectional area normal to flow, ft^2
L_m = mean length of heat flow path, ft
Δt = overall temperature difference, °F
R = thermal resistance, °F·h/Btu

The *thermal resistance* R is directly proportional to the mean length of the heat flow path L_m and inversely proportional to the conductivity k, and the mean cross-sectional area normal to the flow A_m. Equations for thermal resistances of a few common shapes are given in Table 2. Mathematical solutions to many heat conduction problems are addressed by Carslaw and Jaeger (1959). Complicated problems can be solved by graphical or numerical methods such as described by Croft and Lilley (1977), Adams and Rogers (1973), and Patankar (1980).

Equation (2) is analogous to Ohm's law for electrical circuits: thermal current (heat flow) in a thermal circuit is directly proportional to the thermal potential (temperature difference) and inversely proportional to the thermal resistance. This electrical-thermal analogy can be used for heat conduction in complex shapes that resist solution by exact analytical means. The thermal circuit concept is also useful for problems involving combined conduction, convection, and radiation.

OVERALL HEAT TRANSFER

In most steady-state heat transfer problems, more than one heat transfer mode may be involved. The various heat transfer coefficients may be combined into an overall coefficient so that the total heat transfer can be calculated from the terminal temperatures. The solution to this problem is much simpler if the concept of *thermal circuit* and *thermal resistance* is employed.

Local Overall Coefficient of Heat Transfer—Resistance Method

Consider heat transfer from one fluid to another by a three-step steady-state process: from a warmer fluid to a solid wall, through the wall, then to a colder fluid. An *overall coefficient* of heat transfer U based on the difference between the bulk temperatures of the two fluids $t_1 - t_2$ is defined:

$$q = U A (t_1 - t_2) \tag{3}$$

where A is the surface area. Since Equation (3) is a definition of U, the surface area A on which U is based is arbitrary; it should always be specified in referring to U.

The temperature drops across each part of the heat flow path are:

$$t_1 - t_{s1} = qR_1$$
$$t_{s1} - t_{s2} = qR_2$$
$$t_{s2} - t_2 = qR_3$$

where t_{s1} and t_{s2} are the warm and cold surface temperatures of the wall respectively, and R_1, R_2, and R_3 are the thermal resistances. Since the same quantity of heat flows through each thermal resistance, these equations combined give:

$$(t_1 - t_2)/q = (1/UA) = R_1 + R_2 + R_3 \tag{4}$$

Table 2 Solutions for Some Steady-State Thermal Conduction Problems

System	R in Equation $q = \Delta t/R$
Flat wall or curved wall if curvature is small (wall thickness less than 0.1 of inside diameter) 	$R = \frac{L}{kA}$
Radial flow through a right circular cylinder 	$R = \frac{\ln (r_o/r_i)}{2\pi kL}$
Buried cylinder 	$R = \frac{\ln [(a + \sqrt{a^2 - r^2})/r]}{2\pi kL}$ $= \frac{\cosh^{-1}(a/r)}{2\pi kL} (L \gg 2r)$
Radial flow in a hollow sphere 	$R = \frac{(1/r_i - 1/r_o)}{4\pi k}$

L, r, a = dimensions, ft
k = thermal conductivity (at average material temperature, Btu/h·ft^2·°F)
h = heat transfer coefficient, Btu/h·ft^2·°F
A = surface area, ft^2

As shown above, the equations are analogous to those for electrical circuits; for thermal current flowing through n resistances in *series*, the resistances are additive.

$$R_o = R_1 + R_2 + R_3 + \ldots + R_n \quad (5)$$

Similarly, *conductance* is the reciprocal of resistance, and for heat flow through resistances in *parallel*, the conductances are additive:

$$C = (1/R_o) = (1/R_1) + (1/R_2) + (1/R_3) + \ldots + (1/R_n) \quad (6)$$

For convection, the thermal resistance is inversely proportional to the convection coefficient h_c and the applicable surface area:

$$R_c = 1/(h_c A) \quad (7)$$

The thermal resistance for radiation is written similarly to that for convection:

$$R_r = 1/(h_r A) \quad (8)$$

The term *radiation coefficient* h_r has no physical significance but is useful in computations. It is a function of the temperatures, radiation properties, and geometrical arrangement of the enclosure and the body in question.

Analysis by the resistance method can be illustrated by considering heat transfer from air outside to cold water inside an insulated pipe. The temperature gradients and the nature of the resistance analysis are shown in Figure 1.

Since air is sensibly transparent to radiation, some heat transfer occurs by both radiation and convection to the outer insulation surface. The mechanisms act in parallel on the air side. The total transfer then passes through the insulating layer and the pipe wall by thermal conduction, and then by convection and radiation into the cold water stream. (Radiation is not significant on the water side as liquids are sensibly opaque to radiation, although water transmits energy in the visible region.) The contact resistance between the insulation and the pipe wall is assumed negligible.

The heat transfer rate for a given length L of pipe q_{rc} may be thought of as the sum of the rates q_r and q_c flowing through the parallel resistances R_r and R_c associated with the surface radiation and convection coefficients. The total flow then proceeds through the resistance offered to thermal conduction by the insulation R_3, through the pipe wall resistance R_2, and into the water stream through the convection resistance R_1. Note the analogy to direct current electricity. A temperature (potential) drop is required to overcome resistances to the flow of thermal current. The total resistance to heat transfer R_o is the sum of the individual resistances:

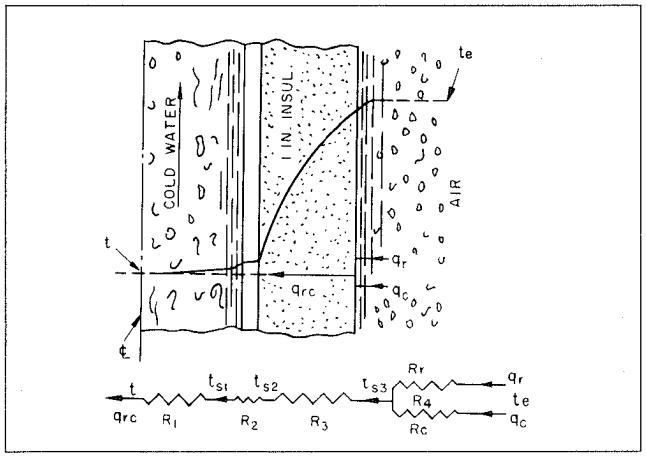

Fig. 1 Thermal Circuit Diagram for Insulated Cold Water Line

$$R_o = R_1 + R_2 + R_3 + R_4 \quad (9)$$

where the resultant parallel resistance R_4 is obtained from:

$$(1/R_4) = (1/R_r) + (1/R_c) \quad (10)$$

If the individual resistances can be evaluated, the total resistance can be obtained from this relation. The heat transfer rate for the length of pipe L can be established by:

$$q_{rc} = (t_e - t)/R_o \quad (11)$$

For a unit length of the pipe, the heat transfer rate is:

$$q_{rc}/L = (t_e - t)/R_o L \quad (12)$$

The temperature drop Δt through each individual resistance may then be calculated from the relation:

$$\Delta t_n = R_n q_{rc} \quad (13)$$

where n = 1, 2, and 3.

Mean Temperature Difference

When heat is exchanged between two fluids flowing through a heat exchanger, the local temperature difference Δt varies along the flow path. Heat transfer may be calculated using:

$$q = UA\Delta t_m \quad (14)$$

where U is the overall coefficient of heat transfer from fluid to fluid, A is an area associated with the coefficient U, and Δt_m is the appropriate mean temperature difference.

For parallel flow or counterflow exchangers and for any exchanger in which one fluid temperature is substantially constant, the mean temperature difference is:

$$\Delta t_m = \frac{\Delta t_1 - \Delta t_2}{\ln(\Delta t_1/\Delta t_2)} = \frac{\Delta t_1 - \Delta t_2}{2.3 \log(\Delta t_1/\Delta t_2)} \quad (15)$$

where Δt_1 and Δt_2 are the temperature differences between the fluids at each end of the heat exchanger. Δt_m is called the *logarithmic mean temperature difference*. For the special case of $\Delta t_1 = \Delta t_2$, which leads to an indeterminate form of Equation (15), $\Delta t_m = \Delta t_1 = \Delta t_2$.

Equation (15) for Δt_m is true only if the overall coefficient and the specific heat of the fluids are constant through the heat exchanger, and no heat losses occur (often well-approximated in practice). Parker *et al.* (1969) give a procedure for cases with variable overall coefficient U.

Calculations using Equation (14) and Δt_m are convenient when terminal temperatures are known. In many cases, however, the temperatures of the fluids leaving the exchanger are not known. To avoid trial-and-error calculations, an alternate method involves the use of three nondimensional parameters, defined as follows:

1. *Exchanger Heat Transfer Effectiveness* ϵ

$$\epsilon = \frac{(t_{hi} - t_{ho})}{(t_{hi} - t_{ci})} \quad \text{when } C_h = C_{min}$$

$$\epsilon = \frac{(t_{co} - t_{ci})}{(t_{hi} - t_{ci})} \quad \text{when } C_c = C_{min} \tag{16}$$

where

$C_h = (\dot{m} c_p)_h$ = hot fluid capacity rate, Btu/h·°F
$C_c = (\dot{m} c_p)_c$ = cold fluid capacity rate, Btu/h·°F
C_{min} = smaller of two capacity rates
t_h = terminal temperature of hot fluid, °F. Subscript *i* indicates entering condition; subscript *o* indicates leaving condition.
t_c = terminal temperature of cold fluid, °F. Subscripts *i* and *o* are the same as for t_h.

2. *Number of Exchanger Heat Transfer Units* (NTU)

$$\text{NTU} = AU_{avg}/C_{min} = (1/C_{min}) \int_A U(dA) \tag{17}$$

where A is the same area used to define overall coefficient U.

3. *Capacity Rate Ratio Z*

$$Z = C_{min}/C_{max} \tag{18}$$

Generally, the heat transfer effectiveness can be expressed for a given exchanger as a function of the number of transfer units and the capacity rate ratio:

$$\epsilon = f(\text{NTU}, Z, \text{flow arrangement}) \tag{19}$$

The effectiveness is independent of the temperatures in the exchanger. For any exchanger in which the capacity rate ratio Z is zero (where one fluid undergoes a phase change, *e.g.*, in a condenser or evaporator), the effectiveness is:

$$\epsilon = 1 - \exp(-\text{NTU}) \tag{20}$$

Heat transferred can be determined from:

$$q = C_h(t_{hi} - t_{ho}) = C_c(t_{co} - t_{ci}) \tag{21}$$

Combining Equations (16) and (21) produces an expression for heat transfer rate in terms of entering fluid temperatures:

$$q = \epsilon C_{min}(t_{hi} - t_{ci}) \tag{22}$$

The proper mean temperature difference for the rate equation [Equation (14)] is then given by:

$$\Delta t_m = (t_{hi} - t_{ci})\, \epsilon/\text{NTU} \tag{23}$$

The effectiveness for parallel flow exchangers is:

$$\epsilon = \frac{1 - \exp[-\text{NTU}(1 + Z)]}{1 + Z} \tag{24}$$

When, for a parallel flow exchanger, $Z = 1$:

$$\epsilon = \frac{1 - \exp(-2\ \text{NTU})}{2} \tag{25}$$

The effectiveness for counterflow exchangers is:

$$\epsilon = \frac{1 - \exp[-\text{NTU}(1 - Z)]}{1 - Z\exp[-\text{NTU}(1 - Z)]} \tag{26}$$

$$\epsilon = \frac{\text{NTU}}{1 + \text{NTU}} \quad \text{for } Z = 1 \tag{27}$$

Incropera and DeWitt (1985) and Kays and London (1964) show the relations of ϵ, NTU, and Z for other flow arrangements. These authors and Afgan and Schlunder (1974) present graphical representations for convenience.

TRANSIENT HEAT FLOW

Often, the heat transfer and temperature distribution under unsteady state (varying with time) conditions must be known. Examples are: cold storage temperature variations on starting or stopping a refrigeration unit; variation of external air temperature, and solar irradiation affecting the heat load of a cold storage room or wall temperatures; the time required to freeze a given material under certain conditions in a storage room; quick freezing of objects by direct immersion in brines; sudden heating or cooling of fluids and solids from one temperature to a different temperature.

The fundamental equation for unsteady state conduction in solids or fluids in which there is no substantial motion is:

$$\frac{\delta t}{\delta \tau} = \alpha \left(\frac{\delta^2 t}{\delta x^2} + \frac{\delta^2 t}{\delta y^2} + \frac{\delta^2 t}{\delta z^2} \right) \tag{28}$$

where the thermal diffusivity α is the ratio $k/\rho c_p$; k is the thermal conductivity; ρ, the density; and c_p, the specific heat. If α is large (high conductivity, low density, and specific heat or both), heat will diffuse faster.

To predict the rate of temperature change of a body or material being held at constant volume with uniform temperature, such as a well-stirred reservoir of fluid, whose temperature is changing because of a net rate of heat gain or loss, the applicable equation can be written:

$$q_{net} = Mc_v dt/d\tau \tag{29}$$

where M is the mass of the body and c_v is its specific heat at constant volume. q_{net} is algebraic with positive being into the body and negative being out of the body. If the heating occurs at constant pressure, c_v should be replaced by c_p; however, for liquids and solids, c_v and c_p are nearly equal, and c_p can be used with negligible error. The term q_{net} may include heat transfer by conduction, convection, or radiation and is the difference between the rate of heat transfer to and away from the body.

From Equation (28), it is possible to derive expressions for temperature and heat flow variations at different instants and different locations. Most common cases have been solved and presented in graphical forms (Jakob 1957, Schneider 1964, Myers 1971). In other cases, it is simpler to use numerical methods (Croft and Lilley 1977, Patankar 1980). When convective boundary conditions are required in the solution of Equation (28), h values based on steady-state correlations are often used. However, this approach may not be valid when rapid transients are involved.

Estimating Cooling Times

Cooling times for materials can be estimated (McAdams 1954) by Gurnie-Lurie charts (Figures 2, 3, and 4), which are graphical

solutions for the heating or cooling of infinite slabs, infinite cylinders, and spheres. These charts assume an initial uniform temperature distribution and no change of phase. They apply to a body exposed to a constant temperature fluid with a constant surface convection coefficient of h. The charts cannot be used to calculate freezing times because of the change of phase that occurs in freezing.

By using Figures 2, 3, and 4, it is possible to estimate the temperature at any point and the average temperature in a homogeneous mass of material as a function of time in a cooling process. In cooling, it is assumed that no freezing occurs. It is possible to estimate the cooling times for rectangular-shaped solids, cubes, cylinders, and spheres.

From a heat transfer point of view, a cylinder insulated on its ends behaves as a cylinder of infinite length, and a rectangular solid insulated so that only two parallel faces allow heat transfer behaves as an infinite slab. Also, a thin slab or a long, thin cylinder may be considered infinite objects.

Consider a slab of material with insulated edges being cooled. If the cooling time is the time required for the center of the slab to reach a temperature of t_2, the cooling time can be calculated as follows:

1. Evaluate the temperature ratio $(t_c - t_2)/(t_c - t_1)$.

where

t_c = temperature of cooling medium
t_1 = initial product temperature
t_2 = final product center temperature

Note that on Figures 2, 3, and 4, the temperature ratio $(t_c - t_2)/(t_c - t_1)$ is designated as Y to simplify the equations.

2. Determine the radius ratio r/r_m designated as n in Figures 2, 3, and 4.

where

r = distance from centerline
r_m = half thickness of slab

3. Evaluate the resistance ratio k/hr_m designated as m in Figures 2, 3, and 4.

where

k = thermal conductivity of material
h = heat transfer coefficient
r_m = half thickness of slab

4. From Figure 2 for infinite slabs, select the appropriate value of $k\tau/\rho c_p r_m^2$ designated as F_o on Figures 2, 3, and 4.

where

τ = time elapsed
c_p = specific heat
ρ = density

5. Determine τ from the value of $k\tau/\rho c_p r_m^2$.

Temperature Distribution in Finite Objects

Finite objects can be formed from the intersection of infinite objects. For example, the solid of intersection of an infinite cylinder and an infinite slab is a finite cylinder with a length equal to the thickness of the slab and a radius equal to that of the cylinder (Figure 5). Intersection of three infinite slabs with the same thickness produces a cube; intersection of three dissimilar slabs forms a finite rectangular solid.

The temperature in the finite object can be calculated from the temperature ratio Y of the infinite objects that are intersected to form the finite object. The product of temperature ratios of the infinite object is the temperature ratio of the finite object; *e.g.*, for the finite cylinder of Figure 5:

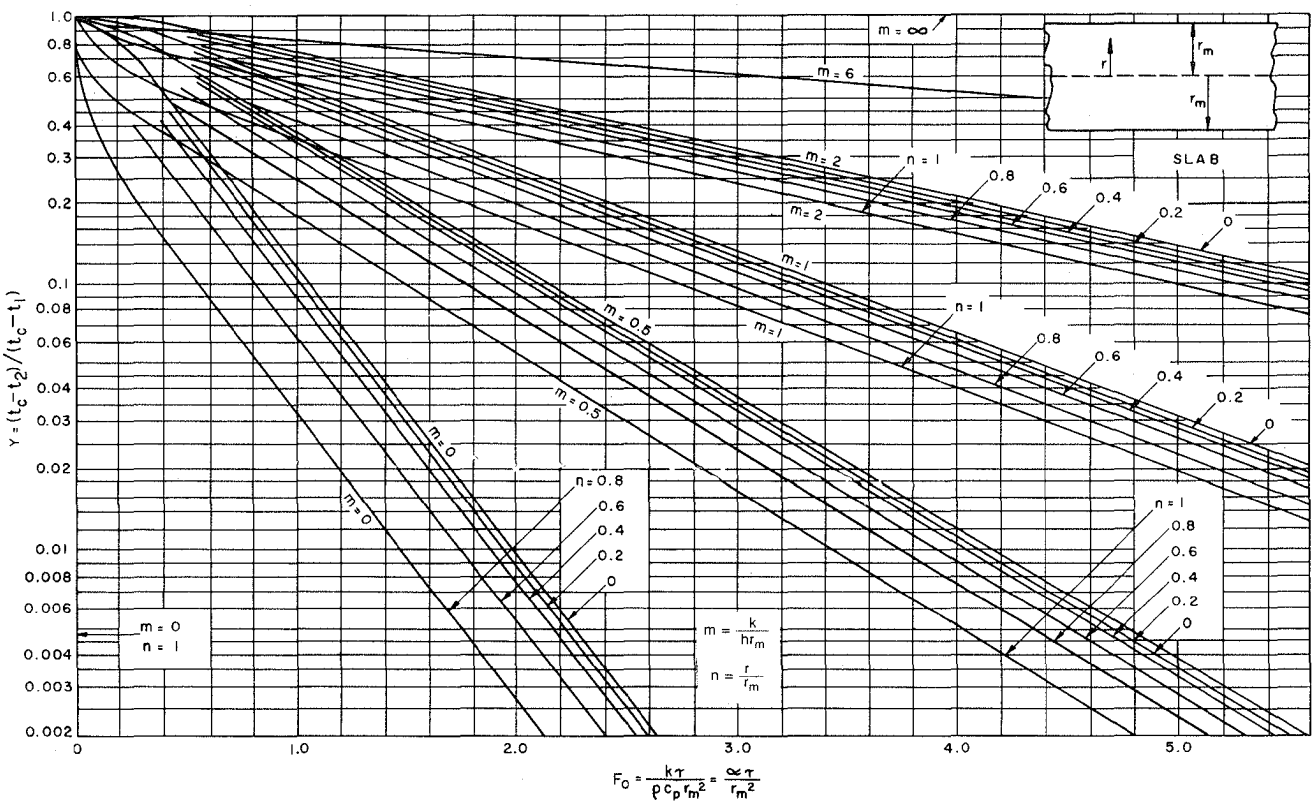

Fig. 2 Transient Temperatures for Infinite Slab

$$Y_{is}\ Y_{ic} = Y_{fc} \quad (30)$$

where

Y_{is} = temperature ratio of infinite slab
Y_{ic} = temperature ratio of infinite cylinder
Y_{fc} = temperature ratio of finite cylinder

For a finite rectangular solid:

$$(Y_{is})_1(Y_{is})_2(Y_{is})_3 = Y_{frs} \quad (31)$$

where

Y_{frs} = temperature ratio of finite rectangular solid, and subscripts 1, 2, and 3 designate three infinite slabs

Heat Exchanger Transients

Determination of the transient behavior of heat exchangers is becoming increasingly important in evaluating the dynamic behavior of heating and air-conditioning systems. Many studies have been made of the transient behavior of counterflow and parallel flow heat exchangers; some are listed in the bibliography.

THERMAL RADIATION

Radiation, one of the basic mechanisms for energy transfer between different temperature regions, is distinguished from conduction and convection in that it does not depend on an intermediate material as a carrier of energy, but is impeded by the presence of material between the regions. The radiation energy transfer process is the consequence of energy-carrying electromagnetic waves, emitted by atoms and molecules resulting from changes in their energy content. The amount and characteristics of radiant energy emitted by a quantity of material depend on the nature of the material, its microscopic arrangement, and its absolute temperature. Although rate of energy emission is independent of the surroundings, the *net* energy transfer rate depends on the temperatures and spatial relationships of the surface and its surroundings.

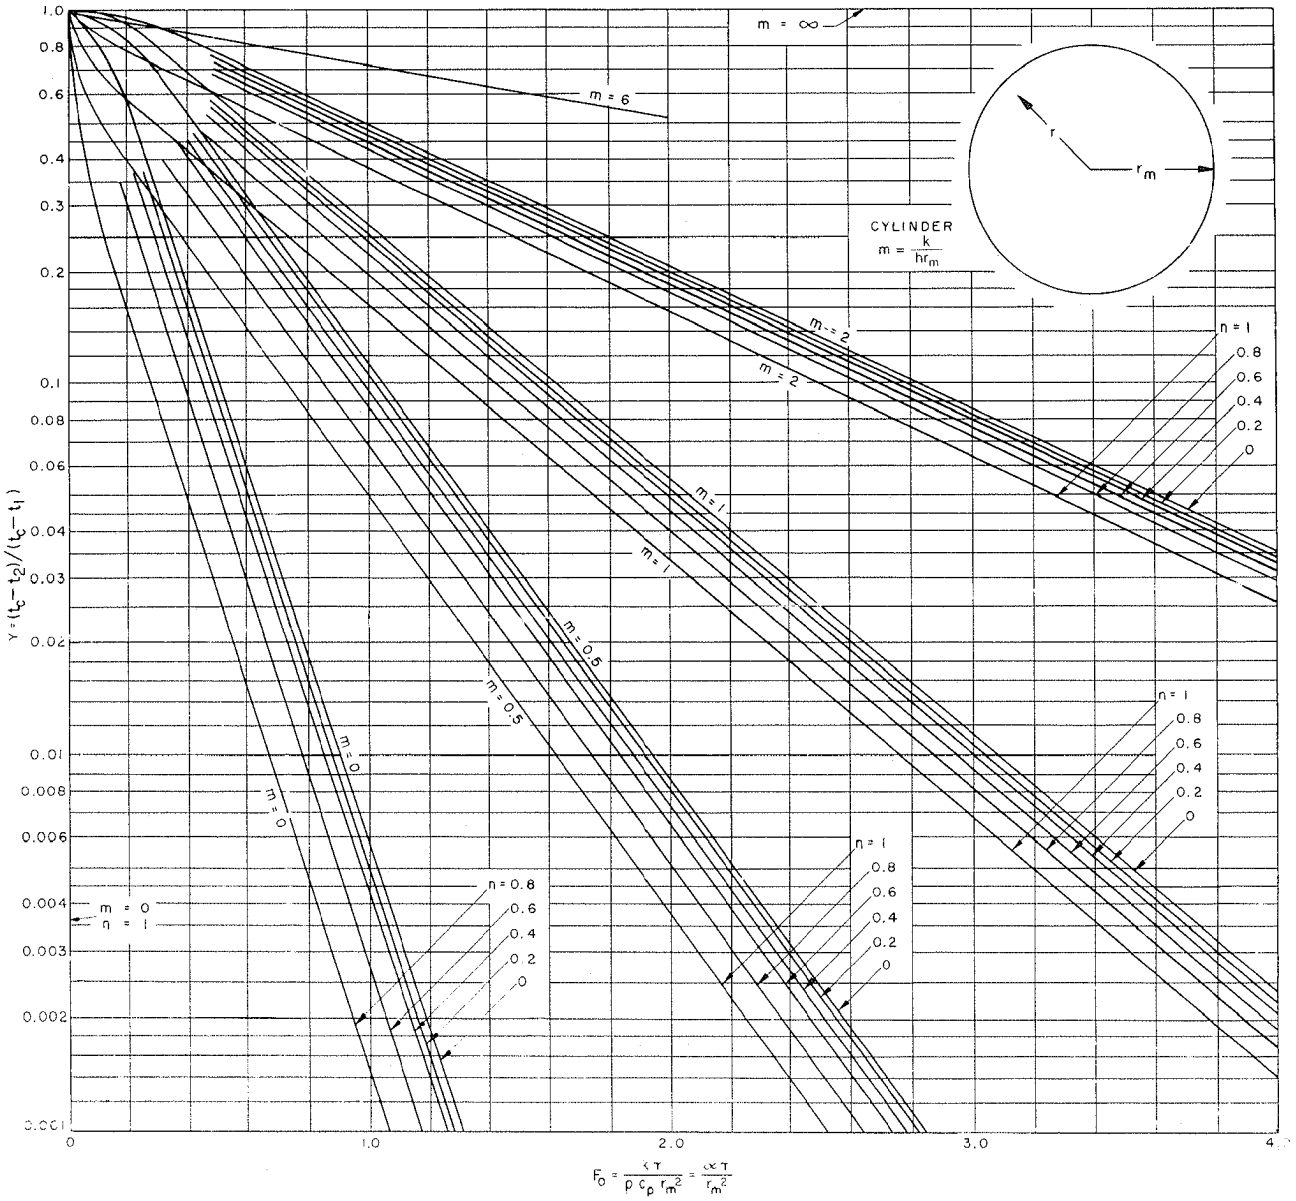

Fig. 3 Transient Temperatures for Infinite Cylinder

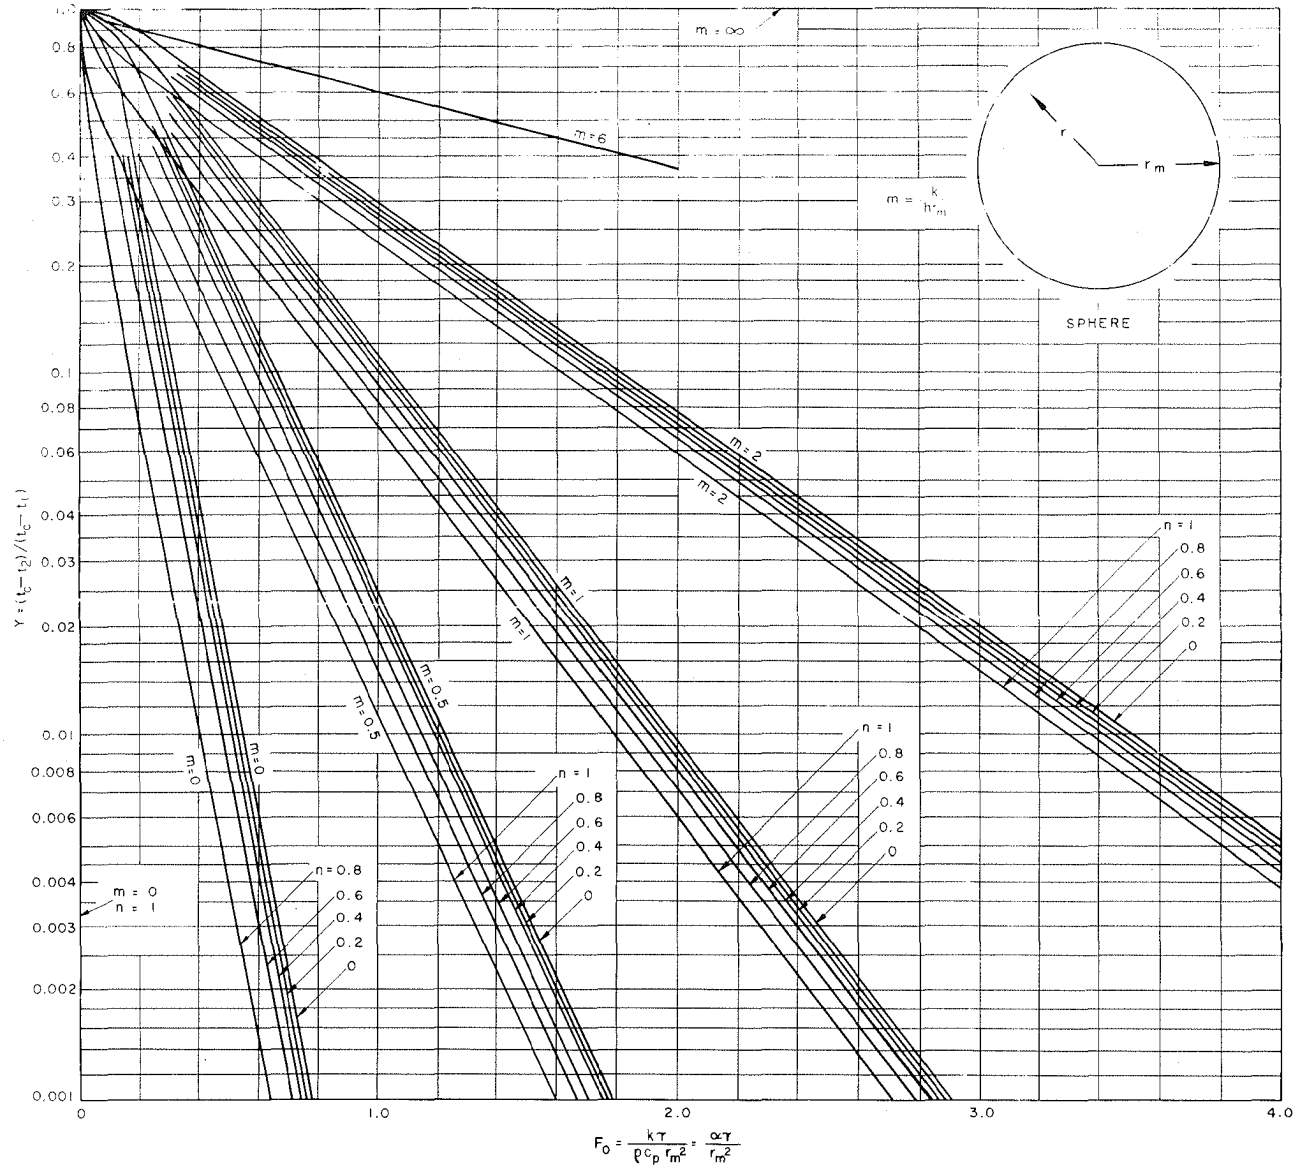

Fig. 4 Transient Temperatures for Spheres

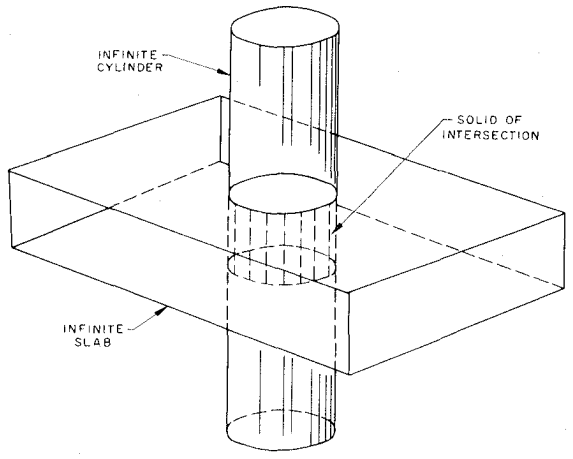

Fig. 5 Finite Cylinder of Intersection from Intersection of Infinite Cylinder and Infinite Slab

Blackbody Radiation

The rate of thermal radiant energy emitted by a surface depends on its absolute temperature. A surface is called *black* if it can absorb all incident radiation. The total energy emitted per unit time per unit area of black surface W_b to the hemispherical region above it is given by the *Stefan-Boltzmann law.*

$$W_b = \sigma T^4 \tag{32}$$

The constant σ is 0.1714×10^{-8} Btu/h·ft²·°R⁴.

The heat radiated by a body is comprised of electromagnetic waves of many different frequencies or wavelengths. Planck showed that the spectral distribution of the energy radiated by a blackbody is given by:

$$W_{b\lambda} = \frac{C_1 \lambda^{-5}}{e^{C_2/\lambda T} - 1} \tag{33}$$

where

$W_{b\lambda}$ = monochromatic emissive power of blackbody, Btu/(h·ft²·μm)
λ_1 = wavelength, μm
T = temperature, °R
C_1 = first Planck's law constant = 1.1870×10^8 Btu·μm⁴/h·ft²
C_2 = second Planck's law constant = 2.5896×10^4 μm·°R

$W_{b\lambda}$ is the *monochromatic emissive power*, defined as the energy emitted per unit time per unit surface area at wavelength λ per unit wavelength interval around λ; *i.e.*, the energy emitted per unit time per unit surface area in the interval $d\lambda$ is equal to $W_{b\lambda}d\lambda$.

The Stefan-Boltzmann equation can be obtained by integrating Planck's equation:

$$W_b = \sigma T^4 = \int_0^\infty W_{b\lambda} d\lambda \tag{34}$$

Wien showed that the wavelength of maximum emissive power multiplied by the absolute temperature is a constant:

$$\lambda_{max} T = 5216\ \mu m \cdot °R \tag{35}$$

This useful relationship gives a rough idea of the spectral energy distribution from a black surface; 25% of the energy is radiated at wavelengths shorter than the maximum, and 75% is radiated at wavelengths longer than the maximum.

Actual Radiation

Substances and surfaces diverge variously from the Stefan-Boltzmann and Planck laws. W_b and $W_{b\lambda}$ are the maximum emissive powers at a surface temperature. Actual surfaces emit and absorb less readily and are called *nonblack*. The emissive power of a nonblack surface, at temperature T, radiating to the hemispherical region above it, is written as:

$$W = \epsilon W_b = \epsilon \sigma T^4 \tag{36}$$

where ϵ is known as the *hemispherical emittance*. The term emittance conforms to physical and electrical terminology; the suffix "ance" denotes a property of a piece of material as it exists. The ending "ivity" denotes a property of the bulk material independent of geometry or surface condition. Thus, emittance, reflectance, absorptance, and transmittance refer to actual pieces of material. Emissivity, reflectivity, absorptivity, and transmissivity refer to the properties of materials that are optically smooth and thick enough to be opaque.

The emittance is a function of the material, the condition of its surface, and the temperature of the surface. Table 3 lists selected values; Siegel and Howell (1981) have more extensive lists.

The monochromatic emissive power of a nonblack surface is similarly written as:

$$W_\lambda = \epsilon_\lambda W_{b\lambda} = \epsilon_\lambda (C_1 \lambda^{-5} / e^{C_2/\lambda T} - 1) \tag{37}$$

where ϵ_λ is the monochromatic hemispherical emittance. The relationship between ϵ and ϵ_λ is given by:

$$W = \epsilon \sigma T^4 = \int_0^\infty W_\lambda d\lambda = \int_0^\infty \epsilon_\lambda W_{b\lambda} d\lambda$$

or

$$\epsilon = (1/\sigma T^4) \int_0^\infty \epsilon_\lambda W_{b\lambda} d\lambda \tag{38}$$

If ϵ_λ does not depend on λ, then, from Equation (38), $\epsilon = \epsilon_\lambda$. Surfaces with this characteristic are called *gray*. Gray surface characteristics are often assumed in calculations. Several classes of surfaces approximate this condition in some regions of the spectrum. The simplicity is desirable, but care must be exercised, especially if temperatures are high. Assumption of grayness is sometimes made because of the absence of information relating ϵ_λ and λ.

When radiant energy falls on a surface, it can be absorbed, reflected, or transmitted through the material. Therefore, from the first law of thermodynamics:

$$\alpha + \tau + \rho = 1 \tag{39}$$

where

α = fraction of incident radiation absorbed or *absorptance*
τ = fraction of incident radiation transmitted or *transmittance*
ρ = fraction of incident radiation reflected or *reflectance*

If the material is opaque, as most solids are in the infrared, $\tau = 0$ and $\alpha + \rho = 1$. For a black surface, $\alpha = 1$, $\rho = 0$, and $\tau = 0$.

Table 3 Emittances and Absorptances for Some Surfaces[a]

Class	Surfaces	Total Normal Emittance[b] At 50 to 100 °F	Total Normal Emittance[b] At 1000 °F	Absorptance for Solar Radiation
1	A small hole in a large box, sphere, furnace, or enclosure	0.97 to 0.99	0.97 to 0.99	0.97 to 0.99
2	Black nonmetallic surfaces such as asphalt, carbon, slate, paint, paper	0.90 to 0.98	0.90 to 0.98	0.85 to 0.98
3	Red brick and tile, concrete and stone, rusty steel and iron, dark paints (red, brown, green, etc.)	0.85 to 0.95	0.75 to 0.90	0.65 to 0.80
4	Yellow and buff, brick and stone, firebrick, fireclay	0.85 to 0.95	0.70 to 0.85	0.50 to 0.70
5	White or light cream brick, tile, paint or paper, plaster, whitewash	0.85 to 0.95	0.60 to 0.75	0.30 to 0.50
6	Window glass	0.90	—	[c]
7	Bright aluminum paint; gilt or bronze paint	0.40 to 0.60	—	0.30 to 0.50
8	Dull brass, copper, or aluminum; galvanized steel; polished iron	0.20 to 0.30	0.30 to 0.50	0.40 to 0.65
9	Polished brass, copper, monel metal	0.02 to 0.05	0.05 to 0.15	0.30 to 0.50
10	Highly polished aluminum, tin plate, nickel, chromium	0.02 to 0.04	0.05 to 0.10	0.10 to 0.40
11	Selective surfaces			
	Stainless steel wire mesh	0.23 to 0.28	—	0.63 to 0.86
	White painted surface	0.92	—	0.23 to 0.49
	Copper treated with solution of $NaClO_2$ and NaOH	0.13	—	0.87
	Copper, nickel, and aluminum plate with CuO coating	0.09 to 0.21	—	0.08 to 0.93

[a] See also Chapter 37, McAdams (1954), and Siegel and Howell (1981).
[b] Hemispherical and normal emittance are not equal in many cases. The hemispherical emittance may be as much as 30% greater for polished reflectors to 7% lower for nonconductors.
[c] Absorbs 4 to 40% depending on its transmittance.

Platinum black and gold black have absorptances of about 98% in the infrared, which is as black as any actual surface is. Any desired degree of blackness can be simulated by a small hole in a large enclosure. Consider a ray of radiant energy entering the opening. It will undergo many internal reflections and be almost completely absorbed before it has a reasonable probability of passing back out of the opening.

Certain flat black paints also exhibit emittances of 98% over a wide range of conditions. They provide a much more durable surface than gold or platinum black and are frequently used on radiation instruments and as standard reference in emittance or reflectance measurements.

Kirchhoff's law, relating emittance and absorptance of any opaque surface from thermodynamic considerations, states that for any surface where the incident radiation is independent of angle or where the surface is diffuse, $\epsilon_\lambda = \alpha_\lambda$. If the surface is gray, or the incident radiation is from a black surface at the same temperature, then also $\epsilon = \alpha$, but many surfaces are not gray. For most surfaces listed in Table 3, absorptance for solar radiation is different than emittance for low-temperature radiation. This is because the wavelength distributions are different in the two cases, and ϵ_λ varies with wavelength.

The foregoing discussion relates to total hemispherical radiation from surfaces. Energy distribution over the hemispherical region above the surface also has an important effect on the rate of heat transfer in various geometric arrangements.

Lambert's law states that the emissive power of radiant energy over a hemispherical surface above the emitting surface varies as the cosine of the angle between the normal to the radiating surface and the line joining the radiating surface to the point of the hemispherical surface. This radiation is *diffuse* radiation. The Lambert emissive power variation is equivalent to assuming that radiation from a surface in a direction other than normal occurs as if it came from an equivalent area with the same emissive power (per unit area) as the original surface. The equivalent area is obtained by projecting the original area onto a plane normal to the direction of radiation. Black surfaces obey the Lambert law exactly. It is approximate for many actual radiation and reflection processes, especially those involving rough surfaces and nonmetallic materials. Most radiation analyses are based on the assumption of gray diffuse radiation and reflection.

In estimating heat transfer rates between surfaces of different geometries, radiation characteristics, and orientations, it is usually assumed that: (1) all surfaces are gray or black, (2) radiation and reflection are diffuse, (3) properties are uniform over the surfaces, (4) absorptance equals emittance and is independent of the temperature of the source of incident radiation, and (5) the material in the space between the radiating surfaces neither emits nor absorbs radiation. These assumptions simplify problems greatly, although results must be considered approximate.

Angle Factor

The distribution of radiation from a surface among the surfaces it irradiates is indicated by a quantity variously called an interception, view, configuration, or angle factor. In terms of two surfaces, i and j, the *angle factor* from surface i to surface j, F_{ij}, is defined as the fraction of diffuse radiant energy leaving surface i that falls directly on j (*i.e.*, is intercepted by j). The angle factor from j to i is similarly defined, merely by interchanging the roles of i and j. This second angle factor will not, in general, be numerically equal to the first. However, $F_{ij}A_i = F_{ji}A_j$, where A is the surface area. Note that a concave surface may *see* itself, $F_{ii} \neq 0$, and that if n surfaces form an enclosure:

$$\sum_{j=1}^{n} F_{ij} = 1 \tag{40}$$

The angle factor F_{12} between two surfaces is:

$$F_{12} = \frac{1}{A_1}\int_{A_1}\int_{A_2}\frac{\cos\phi_1 \cos\phi_2}{\pi r^2}\,dA_1 dA_2 \tag{41}$$

where dA_1 and dA_2 are elemental areas of the two surfaces, r is the distance between dA_1 and dA_2, and ϕ_1 and ϕ_2 are the angles between the respective normals to dA_1 and dA_2 and the connecting line r. Numerical, graphical, and mechanical techniques can solve this equation (Siegel and Howell 1981). Numerical values of angle factor for common geometrics are given in Figure 6.

Calculation of Radiant Exchange between Surfaces Separated by Nonabsorbing Media

A surface radiates energy at a rate independent of its surroundings and absorbs and reflects incident energy at a rate dependent on its surface condition. The net energy exchange per unit area is denoted by q or q_j for unit area of A_j. It is the rate of emission of the surface minus the total rate of absorption at the surface from all radiant effects in its surroundings, possibly including the return of some of its own emission by reflection off its surroundings. The rate at which energy must be supplied to the surface by other exchange processes if its temperature is to remain constant is q; therefore, to define q, the total radiant surroundings (in effect, an enclosure) must be specified.

Several methods have been developed to solve certain problems. To calculate the radiation exchange at each surface of an n opaque surface enclosure by simple, general equations convenient for machine calculation, two terms must be defined:

G = irradiation; total radiation incident on surface per unit time and per unit area

J = radiosity; total radiation that leaves surface per unit time and per unit area

The radiosity is the sum of the energy emitted and the energy reflected:

$$J = \epsilon W_b + \rho G \tag{42}$$

Since the transmittance is zero, the reflectance is:

$$\rho = 1 - \alpha = 1 - \epsilon$$

Thus:

$$J = \epsilon W_b + (1 - \epsilon)G \tag{43}$$

The net energy lost by a surface is the difference between the radiosity and the irradiation:

$$q/A = J - G = \epsilon W_b + (1 - \epsilon)G - G \tag{44}$$

Substituting for G in terms of J from Equation (43):

$$q = \frac{W_b - J}{(1 - \epsilon)/\epsilon\, A} \tag{45}$$

Consider an enclosure of n isothermal surfaces with areas of A_1, A_2, $\cdots$, A_n, emittances of ϵ_1, ϵ_2, $\cdots$, ϵ_n, and reflectances of ρ_1, ρ_2, $\cdots$, ρ_n, respectively.

The irradiation of surface i is the sum of the radiation incident on it from all n surfaces, or

$$G_i A_i = \sum_{j=1}^{n} F_{ji} J_j A_j = \sum_{j=1}^{n} F_{ij} J_j A_i$$

or

$$G_i = \sum_{j=1}^{n} F_{ij} J_j$$

Substituting in Equation (44) yields the following simultaneous equations when each of the n surfaces is considered:

$$J_i = \epsilon_i W_{bi} + (1 - \epsilon_i) \sum_{j=1}^{n} F_{ij} J_j \qquad i = 1, 2, \cdots n \qquad (46)$$

Equation (46) can be solved manually for the unknown Js if the number of surfaces is small. More complex enclosures require a computer.

Once the radiosities (Js) are known, the net radiant energy lost by each surface is determined from Equation (45) as:

$$q_i = \frac{W_{bi} - J_i}{(1 - \epsilon_i)/\epsilon_i A_i}$$

If the surface is black, Equation (45) becomes indeterminate and an alternate expression must be used, such as:

$$q_i = \sum_{j=1}^{n} (J_i A_i F_{ij} - J_j A_j F_{ji})$$

or

$$q_i = \sum_{j=1}^{n} F_{ij} A_i (J_i - J_j) \qquad (47)$$

since

$$F_{ij} A_i = F_{ji} A_j$$

All diffuse radiation processes are included in the aforementioned enclosure method, and surfaces with special characteristics are assigned consistent properties. An opening is treated as an equivalent surface area A_e, with a reflectance of zero. If energy enters the enclosure diffusely through the opening, A_e is assigned

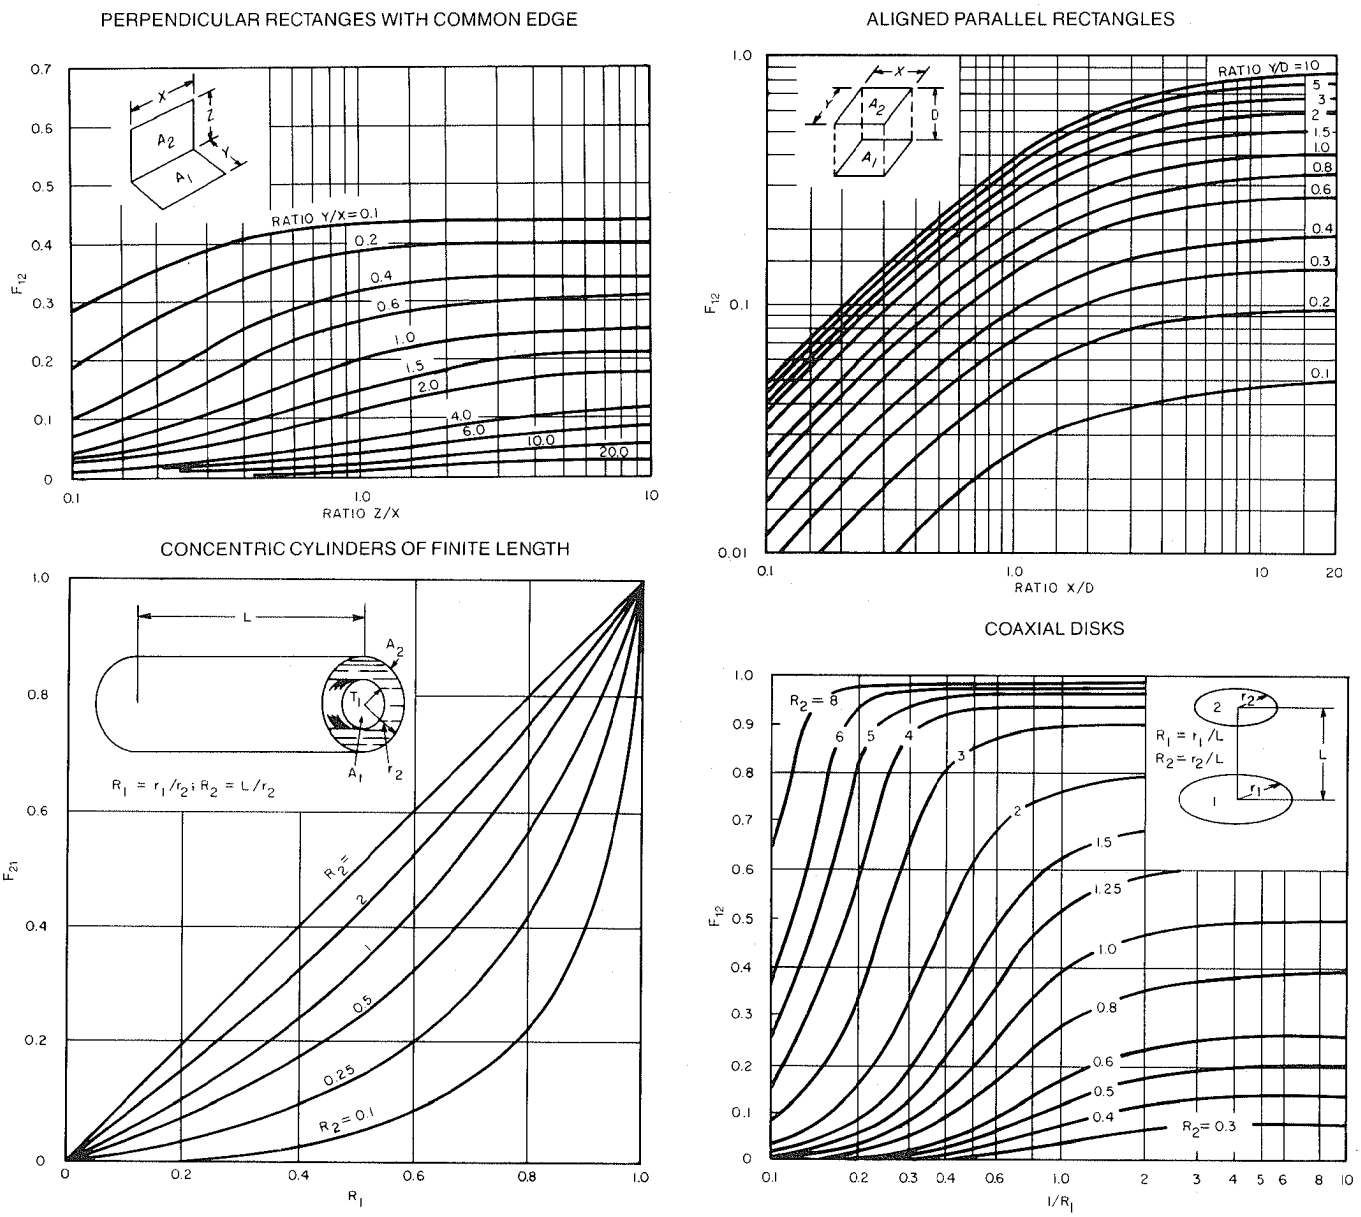

Fig. 6 Radiation Angle Factor for Various Geometries

an equivalent temperature; otherwise, its temperature is taken as zero. If the loss through the opening is desired, q_2 is found. A window in the enclosure is assigned its actual properties.

A surface in *radiant balance* is one for which radiant emission is balanced by radiant absorption; heat is neither removed from nor supplied to a surface. Reradiating surfaces, insulated surfaces with $q_{net} = 0$, can be treated in Equation (46) as being perfectly reflective, $\epsilon = 0$. The equilibrium temperature of such a surface can be found from:

$$T_k = (J_k/\sigma)^{0.25}$$

once Equation (46) has been solved for the radiosities.

Use of angle factors and radiation properties as defined assumes that the surfaces are diffuse radiators—a good assumption for most nonmetals in the infrared region, but a poor assumption for highly polished metals. Subdividing the surfaces and considering the variation of radiation properties with angle of incidence improves the approximation but increases the work required for a solution.

Radiation in Gases

Elementary gases such as oxygen, nitrogen, hydrogen, and helium are essentially transparent to thermal radiation. Their absorption and emission bands are confined mainly to the ultraviolet region of the spectrum. The gaseous vapors of most compounds, however, have absorption bands in the infrared region. Carbon monoxide, carbon dioxide, water vapor, sulfur dioxide, ammonia, acid vapors, and organic vapors absorb and emit significant amounts of energy.

Radiation exchange by opaque solids is considered a surface phenomenon. Radiant energy does, however, penetrate the surface of all materials. The absorption coefficient gives the rate of exponential attenuation of the energy. Metals have large absorption coefficients, and radiant energy penetrates only a few hundred angstroms at most. Absorption coefficients for nonmetals are lower. Radiation may be considered a surface phenomenon unless the material is transparent. Gases have small absorption coefficients, so the path length of radiation through gas becomes very significant.

Beer's law states that the attenuation of radiant energy in a gas is a function of the product of the partial pressure of the gas times the path length ($p_g L$). The monochromatic absorptance of a body of gas of thickness L is then given by:

$$\alpha_{\lambda L} = 1 - e^{-\alpha\lambda L} \tag{48}$$

Since absorption occurs in discrete wavelengths, the absorptances must be summed over the spectral region corresponding to the temperature of the blackbody radiation passing through the gas. The monochromatic absorption coefficient α_λ is also a function of temperature and pressure of the gas; therefore, detailed treatment of gas radiation is quite complex.

Estimated emittance for carbon dioxide and water vapor in air at 75 °F is a function of concentration and path length (Table 4). The values are for a hemispherically shaped body of gas radiating to an element of area at the center of the hemisphere. Among other, Siegel and Howell (1981) and Hottel and Sarofim (1967) describe geometrical calculations in their texts on radiation transfer. Generally, at low values of $p_g L$, the mean path length L, or equivalent hemispherical radius for a gas body radiating to its surrounding surfaces, is four times the mean hydraulic radius of the enclosure. A room with a dimensional ratio of 1:1:4 has a mean path length of 0.89 times the shortest dimension when considering radiation to all walls. For a room with a dimensional ratio of 1:2:6, the mean path length for the gas radiating to all surfaces is 1.2 times the shortest dimension. The mean path length for radiation to the 2 by 6 face is 1.18 times the shortest dimension. These values are for cases where the partial pressure of the gas times the mean path length approaches zero ($p_g L \approx 0$). The factor decreases with increasing values of $p_g L$. For an average room with approximately 8-ft ceilings and relative humidity ranging from 10 to 75% at 75 °F, the effective path length for carbon dioxide radiation is about 85% of the ceiling height, or 6.8 ft. The effective path length for water vapor would be about 93% of the ceiling height, or 7.4 ft. The effective emittance of the water vapor and carbon dioxide radiating to the walls, ceiling, and floor of a room 16 ft by 48 ft with 8-ft walls is in the following tabulation.

Table 4 Emittance of CO_2 and Water Vapor in Air at 75 °F

Path Length, ft	CO_2, % by Volume		Relative Humidity, %			
	0.1	0.3	1.0	10	50	100
10	0.03	0.06	0.09	0.06	0.17	0.22
100	0.09	0.12	0.16	0.22	0.39	0.47
1000	0.16	0.19	0.23	0.47	0.64	0.70

Relative Humidity, %	ϵ_g
10	0.10
50	0.19
75	0.22

The radiation heat transfer from the gas to the walls is then:

$$q = \sigma A_w \epsilon_g (T_g^4 - T_w^4) \tag{49}$$

The examples in Table 4 and the preceding text indicate the importance of gas radiation in environmental heat transfer problems. Gas radiation in large furnaces is the dominant mode of heat transfer, and many additional factors must be considered. Increased pressure broadens the spectral bands, and interaction of different radiating species prohibits simple summation of the emittance factors for the individual species. Departures from blackbody conditions necessitate separate calculations of the emittance and absorptance. McAdams (1954) and Hottel and Sarofim (1967) give more complete treatments of gas radiation.

NATURAL CONVECTION

Heat transfer involving motion in a fluid caused by the difference in density and the action of gravity is called *natural* or *free convection*. Heat transfer coefficients for natural convection are generally much lower than those for forced convection, and it is therefore important not to ignore radiation in calculating the total heat loss or gain. Radiant transfer may be of the same order of magnitude as natural convection, even at room temperatures, since wall temperatures in a room can affect human comfort (Chapter 8).

Natural convection is important in a variety of heating and refrigeration equipment: (1) gravity coils used in high humidity cold storage rooms and in roof-mounted refrigerant condensers, (2) the evaporator and condenser of household refrigerators, (3) baseboard radiators and convectors for space heating, and (4) cooling panels for air conditioning. Natural convection is also involved in heat loss or gain to equipment casings and interconnecting ducts and pipes.

Consider heat transfer by natural convection between a cold fluid and a hot surface. The fluid in immediate contact with the surface is heated by conduction, becomes lighter and rises because of the difference in density of the adjacent fluid. The motion is resisted by the viscosity of the fluid. The heat transfer is influenced

by: (1) gravitational force due to thermal expansion, (2) viscous drag, and (3) thermal diffusion. Gravitational acceleration g, the coefficient of thermal expansion β, the kinematic viscosity $\nu = \mu/\sigma$, and the thermal diffusivity $\alpha = k/\rho c_p$ affect natural convection. These variables are included in the dimensionless numbers, given in Equation (1) of Table 5: the Nusselt number Nu is a function of the product of the Prandtl number Pr and Grashof number Gr. These numbers, when combined, depend on the fluid properties, the temperature difference between the surface and the fluid Δt, and the characteristic length of the surface L. The constant c and the exponent n depend on the physical configuration and the nature of flow.

Natural convection cannot be represented by a single value of exponent n, but can be divided into three regions: (1) *turbulent natural convection*, for which n equals 0.33; (2) *laminar natural convection*, for which n equals 0.25; and (3) a region that has Gr Pr less than for laminar natural convection, for which the exponent n gradually diminishes from 0.25 to lower values. Note that, for wires, the Gr Pr is likely to be very small, so that the exponent n is 0.1 [Equation (5), Table 5].

To calculate the natural convection heat transfer coefficient, determine Gr Pr to find whether the boundary layer is laminar or turbulent; then apply the appropriate equation from Table 5. The correct characteristic length indicated in the table must be used. Since the exponent n is 0.33 for a turbulent boundary layer, the characteristic length cancels out [in Equation (2), Table 5], and the heat transfer coefficient is independent of the characteristic length, as seen in Equations (7), (9), and (11) of Table 5. Turbulence occurs when length or temperature difference is large. Since the length of a pipe is generally greater than its diameter, the heat transfer coefficient for vertical pipes is larger than for horizontal pipes.

Convection from horizontal plates facing downward when heated (or upward when cooled) is a special case. Since the hot air is above the colder air, theoretically no convection should occur. Some convection is caused, however, by secondary influences such as temperature differences on the edges of the plate. As an approximation, a coefficient of somewhat less than half of the coefficient for a heated horizontal plate facing upward can be used.

Since air is often the heat transport fluid, simplified equations for air are given in Table 5. Other information on natural convection is available in the general heat transfer references.

Observed differences in the comparisons of recent experimental and numerical results with existing correlations for natural convective heat transfer coefficients indicate that caution should be taken when applying coefficients for (isolated) vertical plates to vertical surfaces in enclosed spaces (buildings). Bauman *et al.* (1983) and Altmayer *et al.* (1983) developed improved correlations for calculating natural convective heat transfer from vertical surfaces in rooms under certain temperature boundary conditions.

Natural convection can affect the heat transfer coefficient in the presence of weak forced convection. As the forced convection effect (*i.e.*, the Reynolds number) increases, the "mixed convection" (superimposed forced-on-free convection) gives way to the pure forced convection regime. In these cases, other sources describing combined free and forced convection should be consulted, since the heat transfer coefficient in the mixed convection region is often larger than that calculated based on the natural or forced convection calculation alone. Metais and Eckert (1964) summarize natural, mixed, and forced convection regimes for vertical and horizontal tubes. Figure 7 shows the approximate limits for horizontal tubes. Other studies are described by Grigull *et al.* (1982). Local conditions influence the values of the convection coefficient in a mixed convection regime, but the references permit locating the pertinent regime and approximating the convection coefficient.

Table 5 Natural Convection Heat Transfer Coefficients

I. General relationships	$\mathrm{Nu} = c(\mathrm{Gr\ Pr})^n$	(1)
	$h = c\frac{k}{L}\left(\frac{L^3\rho^2\beta g(\Delta t)}{\mu_2}\right)_f^n\left(\frac{\mu c_p}{k}\right)_f^n$	(2)
Characteristic length L for vertical plates, or pipes	L = height	
Horizontal plates	L = length	
Horizontal pipes	L = diameter	
Spheres	L = 0.5 diameter	
Rectangular block, with horizontal length L_h and vertical length L_v	$1/L = (1/L_h) + (1/L_v)$	
II. Planes and pipes		
Horizontal or vertical planes, pipes, rectangular blocks, and spheres (excluding horizontal plates facing downward for heating and facing upward for cooling)		
(a) Laminar range, when Gr Pr is between 10^4 and 10^8	$\mathrm{Nu} = 0.56\ (\mathrm{Gr\ Pr})^{0.25}$	(3)
(b) Turbulent range, when Gr Pr is between 10^8 and 10^{12}	$\mathrm{Nu} = 0.13\ (\mathrm{Gr\ Pr})^{0.33}$	(4)
III. Wires		
For horizontal or vertical wires, use L = diameter, for Gr Pr between 10^{-7} and 1	$\mathrm{Nu} = (\mathrm{Gr\ Pr})^{0.1}$	(5)
IV. With air		
$\mathrm{Gr\ Pr} = 1.6 \times 10^6\ L^3(\Delta t)$	(at 70°F, L in ft, Δt in °F)	
(a) Cylinders		
Small cylinder, Laminar range	$h = 0.27\ (\Delta t/L)^{0.25}$	(6)
Large cylinder, Turbulent range	$h = 0.18\ (\Delta t)^{0.33}$	(7)
(b) Vertical plates		
Small plates, Laminar range	$h = 0.29\ (\Delta t/L)^{0.25}$	(8)
Large plates, Turbulent range	$h = 0.19\ (\Delta t)^{0.33}$	(9)
(c) Horizontal plates, facing upward when heated or downward when cooled		
Small plates, Laminar range	$h = 0.27\ (\Delta t/L)^{0.25}$	(10)
Large plates, Turbulent range	$h = 0.22\ (\Delta t)^{0.33}$	(11)
(d) Horizontal plates, facing downward when heated or upward when cooled		
Small plates	$h = 0.12\ (\Delta t/L)^{0.25}$	(12)

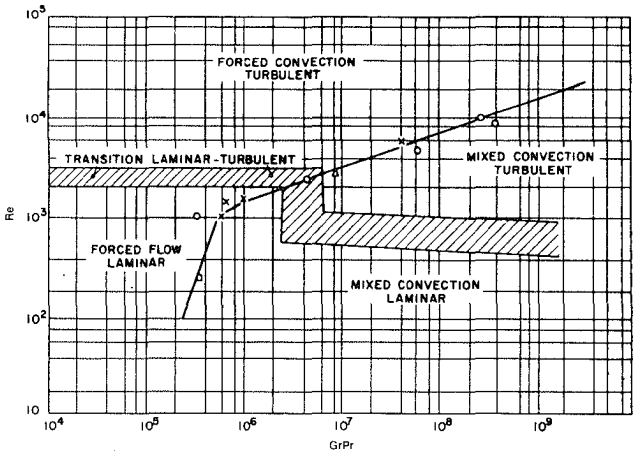

Fig. 7 Regimes of Free, Forced, and Mixed Convection for Flow-through Horizontal Tubes

FORCED CONVECTION

Forced air coolers and heaters, forced air- or water-cooled condensers and evaporators, and liquid suction heat exchangers are examples of equipment that transfer heat primarily by forced convection.

When fluid flows over a flat plate, a *boundary layer* forms adjacent to the plate. The velocity of the fluid at the plate surface is zero and increases to its maximum *free stream* value just past the edge of the boundary layer (Figure 8). Boundary layer formation is important, since the temperature change from plate to fluid (thermal resistance) is concentrated here. Where the boundary layer is thick, thermal resistance is great and the heat transfer coefficient is small. At the leading edge of the plate, boundary layer thickness is theoretically zero, and the heat transfer coefficient is infinite. Flow within the boundary layer immediately downstream from the leading edge is laminar, and is known as *laminar forced convection.* As flow proceeds along the plate, the laminar boundary layer increases in thickness to a critical value. Then, turbulent eddies develop within the boundary layer, except for a thin *laminar sublayer* adjacent to the plate. The boundary layer beyond this point is a *turbulent boundary layer,* and the flow is *turbulent forced convection.* The region between the breakdown of the laminar boundary layer and the establishment of the turbulent boundary layer is the *transition region.* Since the turbulent eddies greatly enhance heat transport into the main stream, the heat transfer coefficient begins to increase rapidly through the transition region. For a flat plate with a smooth leading edge, the turbulent boundary layer starts at Reynolds numbers, based on distance from the leading edge, of about 300,000 to 500,000. In blunt-edged plates, it can start at much smaller Reynolds numbers.

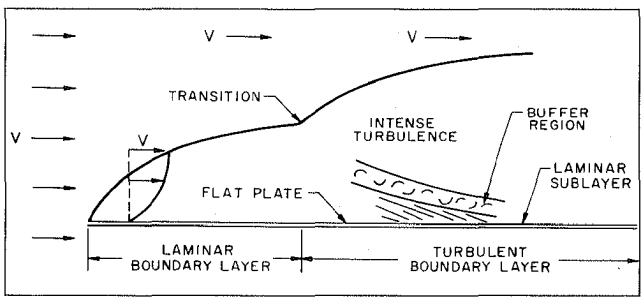

Fig. 8 Boundary Layer Buildup on Flat Plate (Vertical Scale Magnified)

For flow in long tubes or channels of small hydraulic diameter, the laminar boundary layers on each wall grow until they meet, if the velocity is sufficiently low. Beyond this point, the velocity distribution does not change, and no transition to turbulent flow takes place. This is called *fully developed laminar flow.* For tubes of large diameter or at higher velocities, transition to turbulence takes place and *fully developed turbulent flow* is established (Figure 9). Therefore, the length dimension that determines the critical Reynolds number is the hydraulic diameter of the channel. For smooth circular tubes, flow is laminar for Reynolds numbers below 2100 and turbulent above 10,000.

Table 6 lists various forced convection correlations. In the generalized, dimensionless formula of Equation (1), Table 6, heat transfer is determined by flow conditions and by the fluid properties, as indicated by the Reynolds number and the Prandtl number. This equation can be modified to Equation (4), Table 6 to get the *heat transfer factor j.* The heat transfer factor is related to the *friction factor f* by the interrelationship of the transport of momentum and heat, and is approximately $f/2$ for turbulent flow in straight ducts. These factors are plotted in Figure 10.

The characteristic length D is the diameter of the tube, outside or inside, or the length of the plane plate. For other shapes, the hydraulic diameter D_h is used, where:

$$D_h = 2\,r_h = 4\,\frac{\text{Cross-sectional area for flow}}{\text{Total wetted perimeter}}$$

This reduces to twice the distance between surfaces for parallel plates or an annulus.

Simplified equations applicable to common fluids under normal operating conditions appear in Equations (8) through (25) of Table 6. Figure 11 gives graphical solutions for water.

(d) Ammonia gas at approximately 150 °F, 300 psi	Obtained from Eq. (2)			$h = 0.00756\,(G^{0.8}/D^{0.2})$		(11)
at 0 °F, 24 psi	Obtained from Eq. (2)			$h = 0.00604\,(G^{0.8}/D^{0.2})$		(12)
III. Simplified equations for liquids, Turbulent flow inside tubes (Units are in lb_m, h, ft, °F, and Btu.)						
(a) Water at ordinary temperatures, 40 to 200 °F. V is velocity in ft/s, D is tube ID in inches.	McAdams	228	(9-19)	$h = \frac{150\,(1 + 0.011t)\,V^{0.8}}{D^{0.2}}$		(13)
(b) Fluorinated hydrocarbon refrigerant liquid	Obtained from Eq. (2)			$h = c\,(G^{0.8}/D^{0.2})$	(See Note b)	(14)
(c) Ammonia liquid at approximately 100 °F	Obtained from Eq. (2)			$h = 0.0156\,(G^{0.8}/D^{0.2})$		(15)
(d) Oil heating, Approximate equation	Brown and Marco	146	(7-15)	$h = 0.034\,V/\mu_f^{0.63}$		(16)
(e) Oil cooling, Approximate equation	Brown and Marco	146	(7-15)	$h = 0.0255\,V/\mu_f^{0.63}$		(17)
IV. Simplified equations for air						
(a) Vertical plane surfaces, V of 16 to 100 fps (room temperature)[c]	McAdams	249	(9-42)	$h' = 0.5\,(V)^{0.78}$		(18)
(b) Vertical plane surfaces, $V < 16$ fps (room temperature)[c]	McAdams	249	(9-42)	$h' = 0.99 + 0.21\,V$		(19)
(c) Single cylinder cross flow (film temperature = 200 °F) $1000 < GD/\mu_f < 50{,}000$	McAdams	261	(10-3c)	$h = 0.026\,(G^{0.6}/D^{0.4})$		(20)
(d) Single sphere $17 < GD/\mu_f < 70{,}000$	McAdams	265	(10-6)	$h = 0.37\frac{k_f}{D}\left(\frac{GD}{\mu_f}\right)^{0.6}$		(21)
V. Gases flowing normal to pipes (dimensionless)						
(a) Single cylinder Re from 0.1 to 1000	McAdams	260	(10-3)	$\frac{hD}{k_f} = 0.32 + 0.43\left(\frac{GD}{\mu}\right)^{0.52}$		(22)
Re from 1000 to 50,000	McAdams	260	(10-3)	$\frac{hD}{k_f} = 0.24\left(\frac{GD}{\mu_f}\right)^{0.6}$		(23)
(b) Unbaffled staggered tubes, 10 rows, Approximate equation for turbulent flow[d]	McAdams	272	(10-11a)	$\frac{hD}{k_f} = 0.33\left(\frac{G_{max}D}{\mu_f}\right)^{0.6}\left(\frac{\mu c_p}{k}\right)_f^{1/3}$		(24)
(c) Unbaffled in-line tubes, 10 rows, Approximate equation for turbulent flow[d] ($G_{max}D/\mu_f$) from 2000 to 32,000	McAdams	272	(10-11a)	$\frac{hD}{k_f} = 0.26\left(\frac{G_{max}D}{\mu_f}\right)^{0.6}\left(\frac{\mu c_p}{k}\right)_f^{1/3}$		(25)

[a] McAdams (1954) recommends this equation for heating and cooling. Others recommend an exponent of 0.4 for heating and 0.3 for cooling.
[b] Table 7, 1981 ASHRAE *Handbook*, lists values for c.
[c] h' is expressed in Btu/h · ft² · °F based on initial temperature difference.
[d] G_{max} is based on *minimum* free area. Coefficients for tube banks depend greatly on geometrical details. These values approximate only.

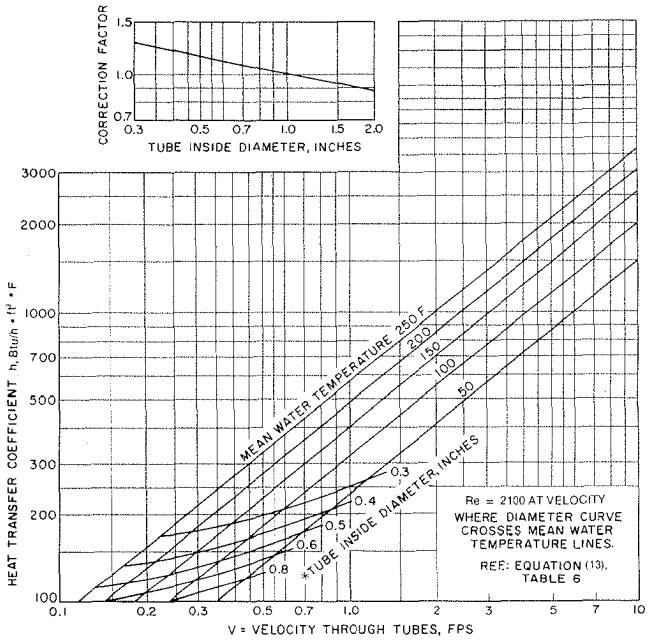

Fig. 11 Heat Transfer Coefficient for Turbulent Flow of Water Inside Tubes

Techniques to Augment Forced Convection

As discussed by Bergles (1985), techniques applied to augment heat transfer can be classified as passive methods, which require no direct application of external power, or as active schemes, which require external power. Examples of passive techniques include rough surfaces, extended surfaces, displaced promoters, and vortex flow devices. Examples of active techniques include mechanical aids, surface vibration, fluid vibration, and electrostatic fields. The effectiveness of a given augmentation technique depends largely on the mode of heat transfer or the type of heat exchanger to which it is applied.

When augmentation is used, the dominant thermal resistances in Equation (9) should be considered, *i.e.*, do not invest in a reduction of already low thermal resistance (increase of an already high heat transfer coefficient). Additionally, heat exchangers with a large number of heat transfer units (NTU) show relatively small gains in effectiveness with augmentation [see Equations (26) and (27)]. Finally, the increased friction factor that accompanies the heat transfer augmentation must be considered.

Several examples of tubes with internal roughness or fins are shown in Figure 12. Rough surfaces of the spiral repeated rib variety are widely used to improve in-tube heat transfer with water, as in flooded chillers. The roughness may be produced by spirally indenting the outer wall, forming the inner wall, or inserting coils. Internal fins in tubes, longitudinal or spiral, can be produced by extrusion or forming, with a substantial increase in the surface area. The fin efficiency, discussed in the next section, can usually be taken as unity. Twisted strips can be inserted as original equipment or as retrofit devices.

The increased friction factor may not require increased heat loss or pumping power if the flow rate can be adjusted or if the length of the heat exchanger can be reduced. Nelson and Bergles (1986) discuss this issue of performance evaluation criteria, especially for HVAC applications.

Of concern in chilled water systems is the fouling that in some cases may seriously reduce the overall heat transfer coefficient U. In general, fouled enhanced tubes still perform better than fouled plain tubes, as shown in recent studies of scaling of cooling tower water (Knudsen and Roy 1983) and particulate fouling (Somerscales *et al.* 1991).

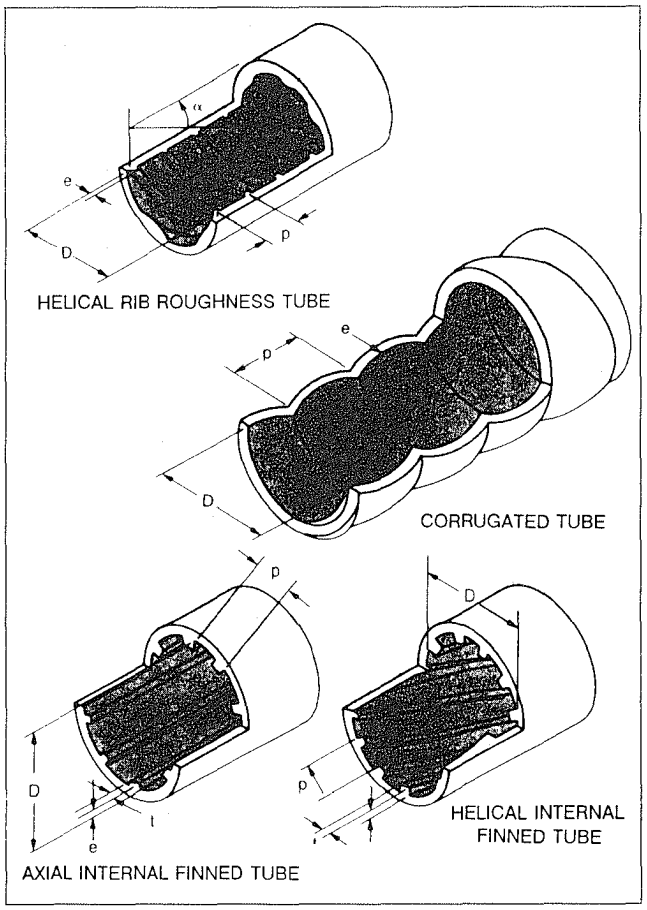

Fig. 12 Typical Tube-Side Enhancements

Fire-tube boilers are frequently fitted with turbulators to improve the turbulent convective heat transfer coefficient constituting the dominant thermal resistance. Also, due to the high gas temperatures, radiation from the connectively heated insert to the tube wall can represent as much as 50% of the total heat transfer. (Note, however, that the magnitude of the convective contribution decreases as the radiative contribution increases because of the reduced temperature difference.) Two commercial bent strip inserts, a twisted strip insert, and a simple bent tab insert are depicted in Figure 13. Design equations, for convection only, are included in Table 7. Beckermann and Goldschmidt (1986) present procedures to include radiation, and Junkhan *et al.* (1985, 1988) give friction factor data and performance evaluations.

Several enhanced surfaces for gases are depicted in Figure 14. The offset strip fin is an example of an interrupted fin that is often found in compact plate fin heat exchangers used for heat recovery from exhaust air. Design equations are included in Table 7. These equations are comprehensive in that they apply to laminar and transitional flow as well as to turbulent flow, which is a necessary feature because the small hydraulic diameter of these surfaces drives the Reynolds number down. Data for other surfaces (wavy, spine, louvered, etc.) are given in the section References.

Among the various active augmentation techniques several mechanical aids, including stirring of the fluid by mechanical means, rotating the heat transfer surface, and use of electrostatic fields have significantly increased the forced convective heat transfer. While mechanical aids are used in appropriate applications such as surface scraping, baking, and drying processes, the electrostatic technique has only been demonstrated on prototype heat exchangers. The electrostatic (also called the electrohydrodynamic

Table 7 Equations for Augmented Forced Convection

or EHD) augmentation technique uses electrically induced secondary motions to destabilize the thermal boundary layer near the heat transfer surface, thereby substantially increasing the heat transfer coefficients at the wall. The magnitude and nature of enhancements are a function of (1) electric field parameters (such as field potential, field polarity, pulse versus steady discharge, electrode geometry and spacing); (2) flow field parameters (such as mass flow rate, temperature, density, and electrical permittivity of the working fluid); and (3) the heat transfer surface type (such as smooth, porous, or integrally finned/grooved configurations).

The EHD effect is generally applied by placing wire or plate electrodes parallel and adjacent to the heat transfer surface. Figure 15 presents four electrode configurations for augmentation of forced convection heat transfer in tube flows. A high-voltage electric field charges the electrode and establishes the electrical body forces required to initiate and sustain augmentation.

Several important advantages have contributed to the progress of the EHD technique in recent years. The mechanically complex rotation, injection, and vibration forms of promoters are generally cumbersome to manufacture. Furthermore, these systems often require a significant fraction of the power needed to pump the fluid. In contrast, even though high voltages are employed, the amount of electrical power consumed by the EHD process is extremely small (a few watts or less) due to the very small currents (1 mA or less). The additional manufacturing costs are minimal as the EHD process requires a small transformer and simple wire or plate electrodes. As is the case with most augmentation techniques, the increase in heat transfer coefficients is associated with a corresponding increase in pressure drop coefficients. However, unlike most other techniques where the pressure drop is substantial, the rise in pressure drops in the EHD technique is usually much less than the corresponding increase in heat transfer coefficients.

The EHD technique is limited in that it is only effective for fluids with low electrical conductivity. This includes air, certain industrial fluids, and many refrigerants. Table 8 provides a summary of selected studies involving single-phase and phase-change processes, and demonstrates that the EHD technique is particularly effective for heat transfer enhancement of refrigerants, including the ozone-safe refrigerant substitutes. Ohadi (1991b) gives further details on the fundamentals, applicability, and limitations of the EHD technique.

EXTENDED SURFACE

Heat transfer from a prime surface can be increased by attaching *fins* or *extended surfaces* to increase the area available for heat transfer. Fins provide a more compact heat exchanger with lower material costs for a given performance. To achieve optimum design, fins are generally located on the side of the heat exchanger where the heat transfer coefficients are low (such as the air side of an air-to-water coil). Equipment with an extended surface includes natural and forced convection coils and shell-and-tube evaporators and condensers. Fins are also used inside tubes in condensers and dry expansion evaporators.

Fin Efficiency

As heat flows from the root of a fin to its tip, temperature drops because of the thermal resistance of the fin material. The temperature difference between the fin and the surrounding fluid is therefore greater at the root than at the tip, causing a corresponding variation in the heat flux. Therefore, increases in fin length result in proportionately less additional heat transfer. To account for this effect, *fin efficiency* is defined by Equation (50) as the ratio of the actual heat transferred from the fin to the heat that would be transferred if the entire fin were at its root or base temperature.

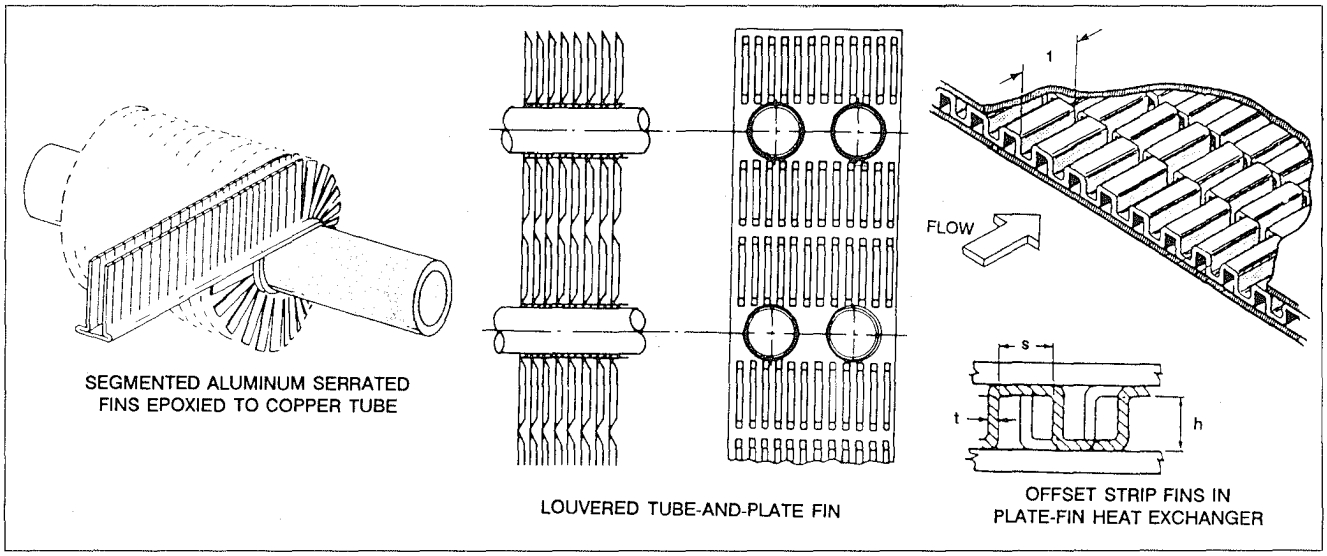

Fig. 14 Enhanced Surfaces for Gases

Table 8 EHD Heat Transfer Enhancement in Heat Exchangers

Source	Maximum Reported Enhancement, %	Test Fluid	Heat Transfer Wall/ Electrode Configuration	Process
Fernandez (1987)	2300	Transformer oil	Tube/wire	Forced convection
Ohadi *et al.* (1991)	320	Air	Tube/wire or rod	Forced convection
Ohadi *et al.* (1992)	480	R-123	Tube/wire	Boiling
Sunada *et al.* (1991)	600	R-123	Vertical wall/plate	Condensation

Yabe and Maki (1988)	10,000	96% (by mass) R-113, 4% ethanol	Plate/ring	Natural convection

$$\phi = \frac{\int h(t - t_e)dA}{\int h(t_r - t_e)dA} \quad (50)$$

where ϕ is the fin efficiency, t_e is the temperature of the surrounding environment, and t_r is the temperature at the fin root. Fin efficiency is low for long fins, thin fins, or fins of low thermal conductivity material. Fin efficiency decreases as the heat transfer coefficient increases because of the increased heat flow. For natural convection in air-cooled condensers and evaporators, where h for the air side is low, fins can be fairly large and of low conductivity materials, such as steel, instead of copper or aluminum. For condensing and boiling, where large heat transfer coefficients are involved, fins must be very short for optimum use of material.

The heat transfer from a finned surface, such as a tube, which includes both finned or secondary area A_s and unfinned or prime area A_p is given by Equation (51):

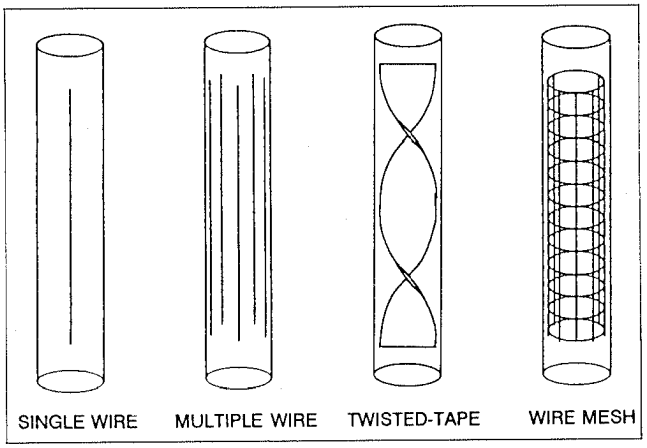

Fig. 15 Electrode Configurations for Internal Forced-Convection Flow

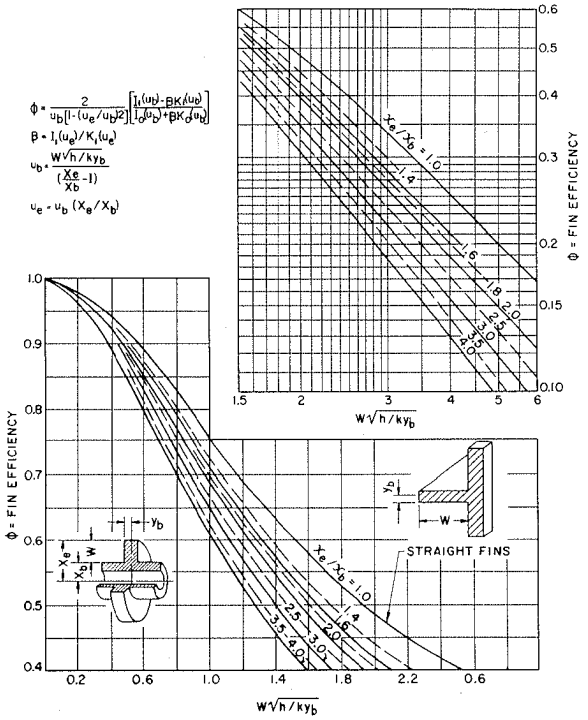

Fig. 16 Efficiency of Annular Fins of Constant Thickness

$$q = (h_p A_p + \phi h_s A_s)(t_r - t_e) \quad (51)$$

Assuming the heat transfer coefficients for the finned surface and prime surface are equal, a *surface efficiency* ϕ_s can be derived for use in Equation (52).

$$\phi_s = 1 - (A_s/A)(1 - \phi) \quad (52)$$

$$q = \phi_s h A (t_r - t_e) \quad (53)$$

where A is the total surface area, equal to the sum of the finned and prime areas.

Temperature distribution and fin efficiencies for various fin shapes are derived in most heat transfer texts. Figures 16 through

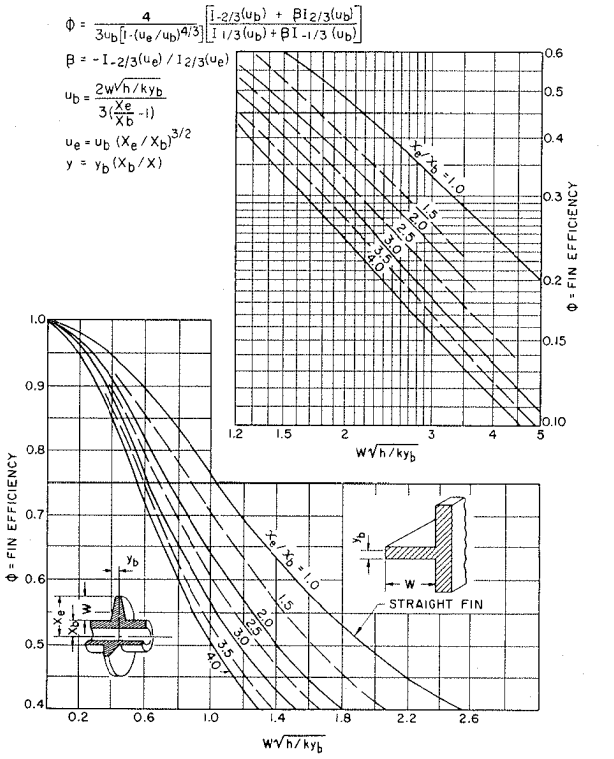

Fig. 17 Efficiency of Annular Fins with Constant Metal Area for Heat Flow

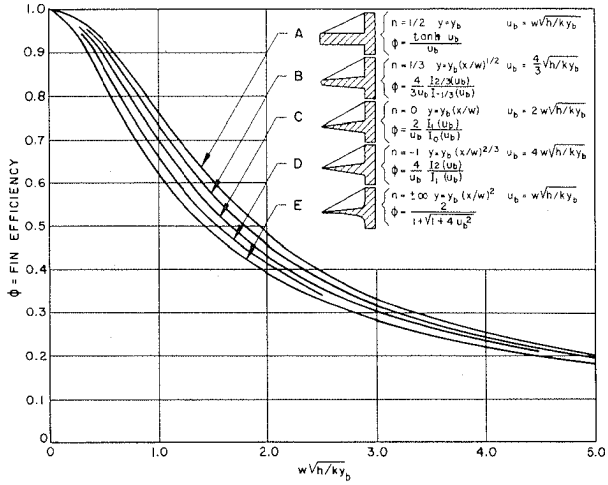

Fig. 18 Efficiency of Several Types of Straight Fin

19 show curves and equations for annular fins, straight fins, and spines. For constant thickness square fins, the efficiency of a constant thickness annular fin of the same area can be used. More accuracy, particularly with rectangular fins of large aspect ratio, can be obtained by dividing the fin into circular sectors (Rich 1966).

By defining a dimensionless thermal resistance Φ by Equations (54) and (54a) and developing expressions for its maximum limiting value Φ_{max}, Rich (1966) presents results for a wide range of geometries in a compact form for equipment designers.

$$\Phi = R_f t_o k / l^2 \tag{54}$$

$$R_f = (1/h)(1/\phi - 1) \tag{54a}$$

where

Φ = dimensionless thermal resistance
ϕ = fin efficiency
t_o = fin thickness at fin base
l = length dimension = $r_t - r_o$ for annular fins, and
= W for rectangular fins

Figure 20 gives Φ_{max} for annular fins of constant and tapered cross section as a function of $R = r_t/r_o$, *i.e.*, the ratio of the fin tip-to-root radii. Figure 21 gives Φ_{max} for rectangular fins of a given geometry as determined by the sector method. Figure 22 gives correction factors for the determination of Φ from Φ_{max} for both annular and rectangular fins.

Example. This example illustrates the use of the fin resistance number for a rectangular fin typical of that for an air-conditioning coil.

Given: $L = 0.75$ in. $t_o = 0.006$ in.
$W = 0.50$ in. $h = 10$ Btu/h·ft²·°F
$r_o = 0.25$ in. $k = 100$ Btu/h·ft·°F

Solution: From Figure 21 at $W/r_o = 2.0$ and $L/W = 1.5$

$$\Phi_{max} = R_{f(max)} t_o k / W^2 = 1.12$$

$$R_{f(max)} = \frac{1.12 \times 0.50^2}{0.006 \times 100 \times 12} = 0.0389 \frac{\text{h·ft}^2\text{·°F}}{\text{Btu}}$$

The correction factor, which is multiplied by $R_{f(max)}$ to give R_f, is given in Figure 22 as a function of the fin efficiency. As a first approximation, the fin efficiency is calculated from Equation (54a) assuming $R_f = R_{f(max)}$.

$$\phi = 1/(1 + hR_f) \approx 0.72$$

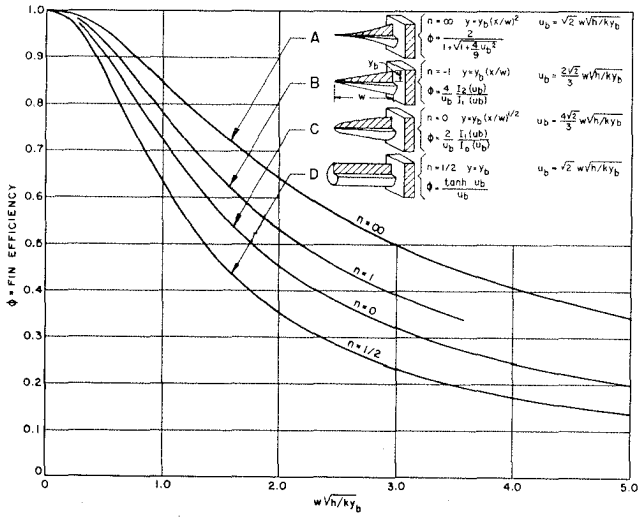

Fig. 19 Efficiency of Four Types of Spine

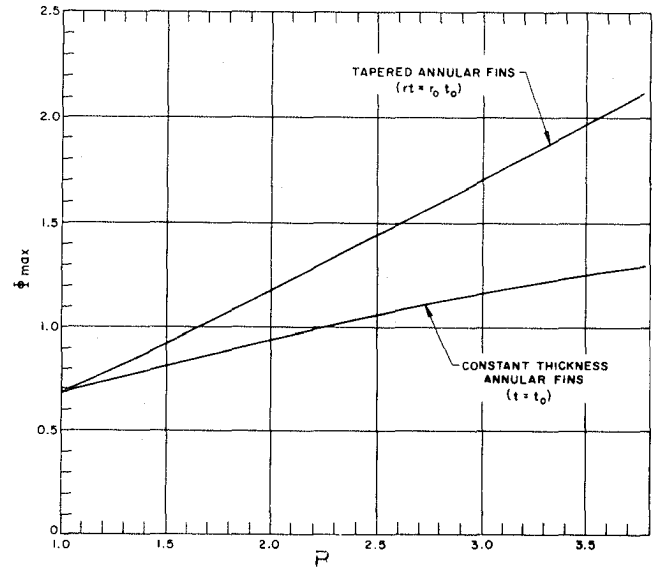

Fig. 20 Maximum Fin Resistance Number of Annular Fins
(Gardner 1945)

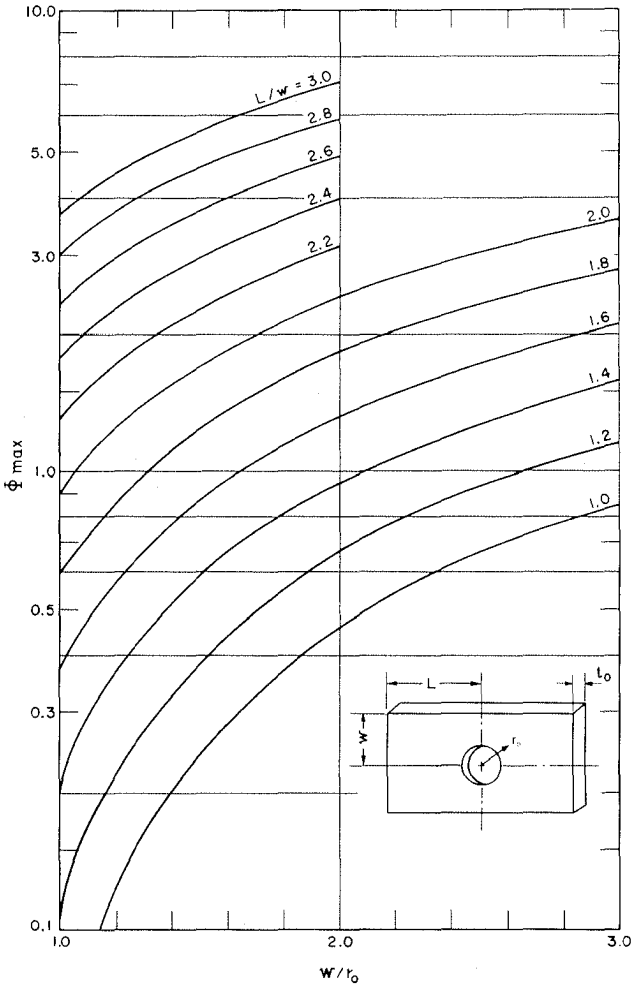

Fig. 21 Maximum Fin Resistance Number of Rectangular Fins Determined by Sector Method

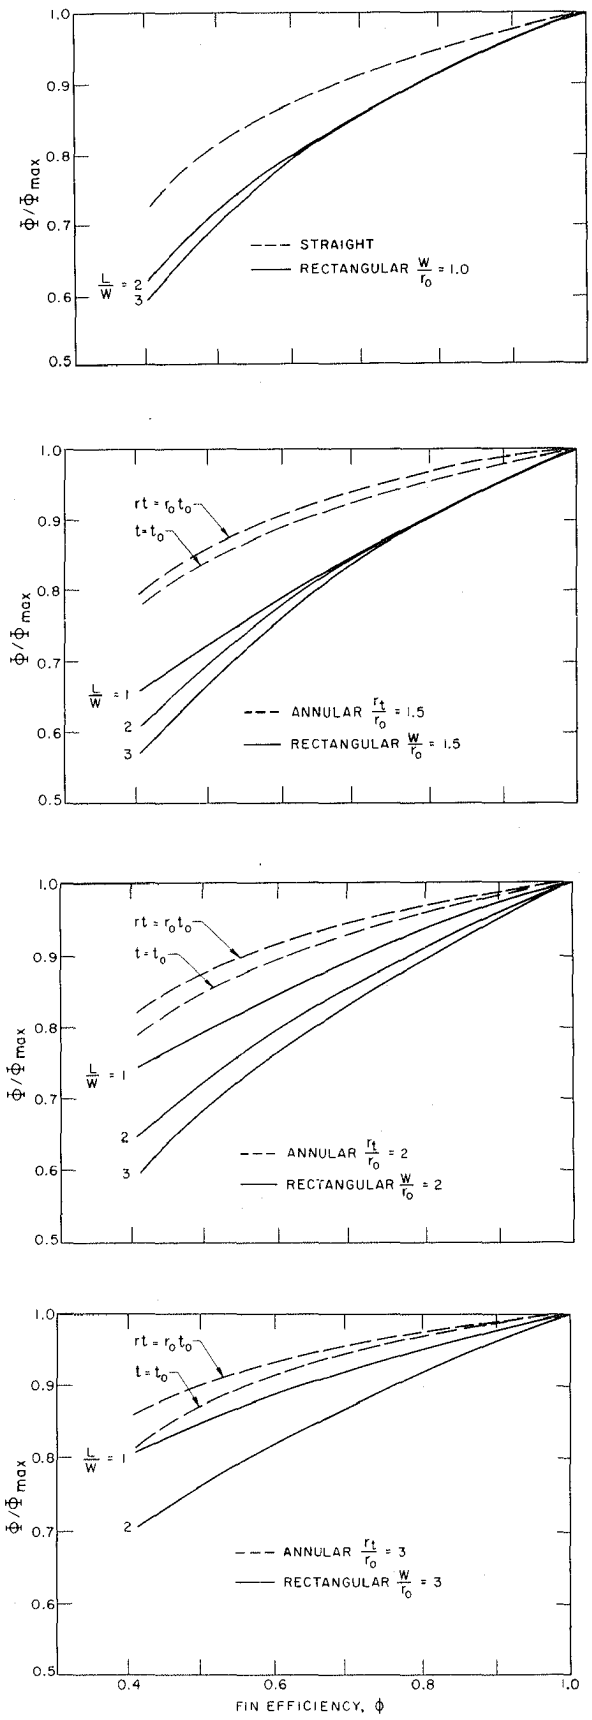

Fig. 22 Variation of Fin Resistance Number with Efficiency for Annular and Rectangular Fins
(Gardner 1945)

Interpolating between $L/W = 1$ and $L/W = 2$ at $W/r_o = 2$ gives:

$$\Phi/\Phi_{max} = 0.88$$

Therefore:

$$R_f = 0.88 \times 0.0389 = 0.0342 \text{ ft}^2 \cdot °\text{F} \cdot \text{h/Btu}$$

The above steps may now be repeated using the corrected value of fin resistance.

$$\phi = 0.745$$
$$\Phi/\Phi_{max} = 0.9$$
$$R_f = 0.035 \text{ ft}^2 \cdot °\text{F} \cdot \text{h/Btu}$$

Note that the improvement in accuracy by reevaluating Φ/Φ_{max} is less than 1% of the overall thermal resistance (environment to fin base). The error produced by using $R_{f(max)}$ without correction is less than 3%. For many practical cases where greater accuracy is not warranted, a single value of R_f, obtained by estimating Φ/Φ_{max}, can be used over a range of heat transfer coefficients for a given fin. For approximate calculations, the fin resistance for other values of k and t_o can be obtained by simple proportion if the range covered is not excessive.

Schmidt (1949) presented approximate, but reasonably accurate, analytical expressions (for computer use) for circular, rectangular, and hexagonal fins. Hexagonal fins are the representative fin shape for the common staggered tube arrangement in finned tube heat exchangers.

Schmidt's empirical solution is given by:

$$\phi = \tanh(mr_i\phi) \; / \; mr_i$$

where $m = (2h/kt)^{0.5}$ and Φ is given by:

$$\phi = [(r_e/r_i) - 1][1 + 0.35 \ln (r_e/r_i)]$$

For *circular fins* $r_e/r_i = r_o/r_i$

and for *rectangular fins*

$$r_e/r_i = 1.28\,\psi\sqrt{(\beta - 0.2)}, \quad \psi = M/r_i, \quad \beta = L/M \geq 1,$$

where M and L are defined by Figure 23 as $a/2$ or $b/2$, depending on which is greater.

For *hexagonal fins* $r_e/r_i = 1.27\,\psi\sqrt{(\beta - 0.3)}$

where ψ and β are defined as above and where M and L are defined by Figure 24 as $a/2$ or b (whichever is less) and $0.5\sqrt{[a^2/2)^2 + b^2}$, or vice versa.

The bibliography lists other sources of information on finned surfaces.

Thermal Contact Resistance

Fins can be extruded from the prime surface—for example, the short fins on the tubes in flooded evaporators or water-cooled con-

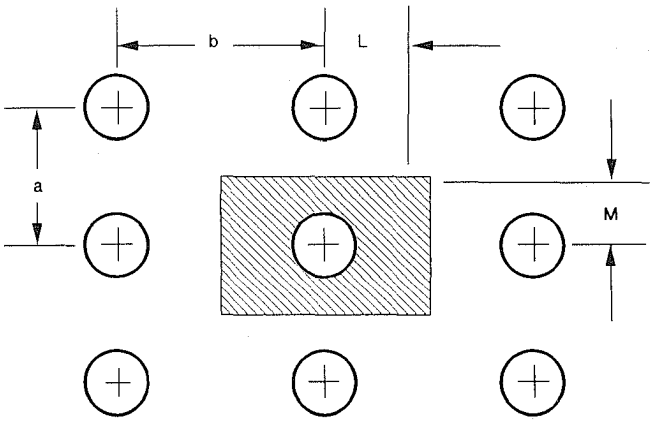

Fig. 23 Rectangular Tube Array

densers; or they can be fabricated separately, sometimes of a different material, and bonded to the prime surface. Metallurgical bonds are achieved by furnace-brazing, dip-brazing, or soldering. Nonmetallic bonding materials, such as epoxy resin, are also used. Mechanical bonds are obtained by tension winding fins around tubes (spiral fins) or expanding the tubes into the fins (plate fin). Metallurgical bonding, properly done, leaves negligible thermal resistance at the joint, but is not always economical. Thermal resistance of a mechanical bond may or may not be negligible, depending on the application, care taken in manufacture, and materials and temperatures involved. Tests of plate fin coils with expanded tubes have indicated that substantial losses in performance can occur with fins that have cracked collars; but negligible thermal resistance was found in coils with continuous collars and properly expanded tubes (Dart 1959).

Thermal resistance at an interface between two solid materials is largely a function of the surface properties and characteristics of the solids, the contact pressure, and the fluid in the interface, if any. Eckels (1977) modeled the influence of fin density, fin thickness, and tube diameter on contact pressure and compared it to data for wet and dry coils. Shlykov (1964) showed that the range of attainable contact resistances is large. Sonokama (1964) presents data on the effects of contact pressure, surface roughness, hardness, void material, and the pressure of the gas in the voids. Lewis and Sauer (1965) show the resistance of adhesive bonds, and Kaspareck (1964) and Clausing (1964) give data on the contact resistance in a vacuum environment.

Finned Tube Heat Transfer

The heat transfer coefficients for finned coils follow the basic equations of convection, condensation, and evaporation. The arrangement of the fins affects the values of constants and the exponential powers in the equations. It is generally necessary to refer to test data for the exact coefficients.

For natural convection finned coils (gravity coils), approximate coefficients can be obtained by considering the coil to be made of tubular and vertical fin surfaces at different temperatures and then applying the natural convection equations to each. This calculation is difficult because the natural convection coefficient depends on the temperature difference, which varies at different points on the fin.

Fin efficiency should be high (80 to 90%) for optimum natural convection heat transfer. A low fin efficiency reduces the temperature near the tip. This reduces Δt near the tip, and also the coefficient, h, which in natural convection depends on Δt. The coefficient of heat transfer also decreases as the fin spacing decreases, because of interfering convection currents from adjacent fins and reduced free-flow passage; 2 to 4 in. spacing is common. Generally, high coefficients result from large temperature differences and small flow restriction.

Edwards and Chaddock (1963) give coefficients for several circular fin-on-tube arrangements, using fin spacing δ as the characteristic length and in the form $\mathrm{Nu} = f(\mathrm{GrPr}\delta/D_o)$ where D_o is the fin diameter.

Forced convection finned coils are used extensively in a wide variety of equipment. The fin efficiency for optimum performance is smaller than that for gravity coils, since the forced convection coefficient is almost independent of the temperature difference between the surface and the fluid. Very low fin efficiencies should be avoided, since inefficient surface gives a high (uneconomical) pressure drop. An efficiency of 70 to 90% is often used.

As fin spacing is decreased to obtain a large surface area for heat transfer, the coefficient generally increases because of higher air velocity between fins at the same face velocity and reduced equivalent diameter. The limit is reached when the boundary layer formed on one fin surface (Figure 8) begins to interfere with the boundary layer formed on the adjacent fin surface, resulting in a decrease of the heat transfer coefficient, which may offset the advantage of larger surface area.

Selection of the fin spacing for forced convection finned coils usually depends on economic and practical considerations, such as fouling, frost formation, condensate drainage, cost, weight, and volume. Fins for conventional coils generally are spaced 14 to 6 per inch, except where factors such as frost formation necessitate wider spacing.

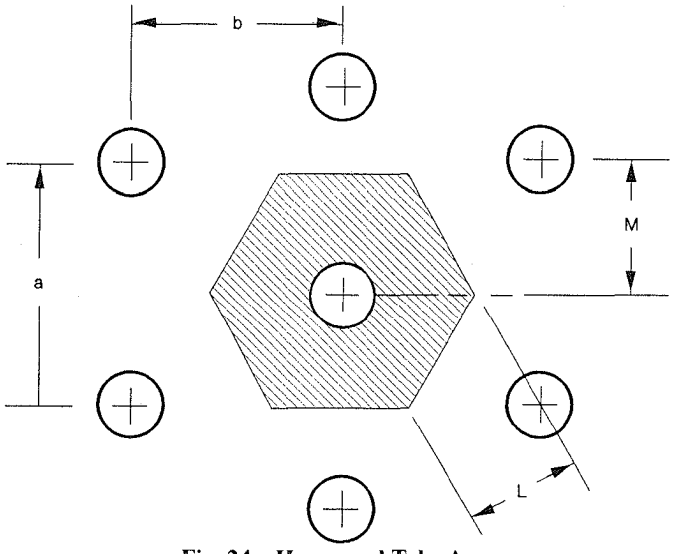

Fig. 24 Hexagonal Tube Array

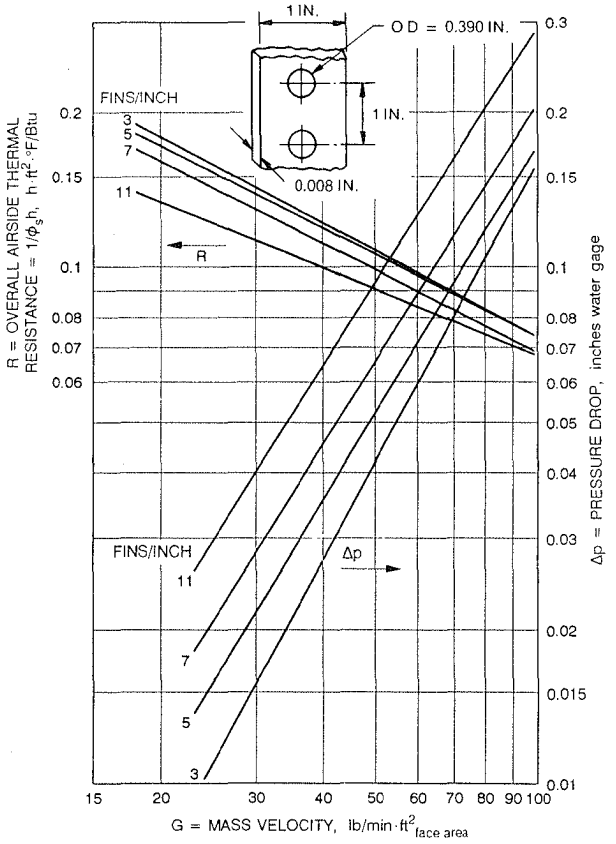

Fig. 25 Overall Air-Side Thermal Resistance and Pressure Drop for 1-Row Coils
(Shepherd 1946)

Several means are used to obtain higher coefficients with a given air velocity and surface, usually by creating air turbulence, generally with a higher pressure drop: (1) staggered tubes instead of in-line tubes for multiple row coils; (2) artificial additional tubes, or collars or fingers made by suitably forming the fin materials; (3) corrugated fins instead of plane fins; and (4) louvered or interrupted fins.

Figure 25 shows data for one-row coils. The thermal resistances plotted include the temperature drop through the fins, based on one square foot of total external surface area.

The bibliography lists other sources of information on fins.

SYMBOLS

A = surface area for heat transfer
A_F = cross-sectional flow area
C = conductance; or fluid capacity rate
c = coefficient or constant
c_p = specific heat at constant pressure
c_v = specific heat at constant volume
C_1, C_2 = Planck's law constants [see Eq. (33)]
D = diameter
d = diameter; or prefix meaning differential
e = emissivity; protuberance height
F = angle factor [see Eqs. (40) and (41)]; fin factor
Fo = Fourier number (see Table 1 and Figs. 2, 3, and 4)
f = friction factor for single-phase flow
G = mass velocity; or irradiation
g = gravitational acceleration
h = heat transfer coefficient; offset strip fin height
J = mechanical equivalent of heat; or radiosity
j = heat transfer factor j [see Eq. (4), Table 6]
k = thermal conductivity
l = length; length of one module of offset strip fins
M = mass; or molecular weight
m = general exponent
$\dot{m}$ = mass rate of flow
N = number of tubes in vertical tier
n = general number [see Eq. (2), Table 5]; or ratio r/r_m (see Figs. 2, 3, and 4)
NTU = number of exchanger heat transfer units [see Eq. (17)]
p = pressure; fin pitch; repeated rib pitch
Q = total heat transfer
q = rate of heat transfer
R = thermal resistance
r = radius
s = lateral spacing of offset fin strips
T = absolute temperature
t = temperature; fin thickness at base
U = overall heat transfer coefficient
V = linear velocity
W = work; or total rate of energy emission
W_λ = monochromatic emissive power
x, y, z = lengths along principal coordinate axes
Y = temperature ratio (see Figs. 2, 3, and 4)
Y_v = mole fraction of vapor
Z = ratio of fluid capacity rates [see Eq. (18)]
α = thermal diffusivity = $k/\rho c_p$ [Eq. (28)]; absorptance; spiral angle for helical fins; aspect ratio of offset strip fins
β = coefficient of thermal expansion; contact angle of rib profile
γ = ratio, l/s
Δ = difference between values
δ = distance between fins; ratio, t/s
ϵ = hemispherical emittance; or exchanger heat transfer effectiveness [see Eq. (16)]
λ = wavelength
μ = absolute viscosity
ν = kinematic viscosity
ρ = density; or reflectance
σ = Stefan-Boltzmann constant
τ = time; or transmittance [see Eq. (39)]
Φ = fin resistance number defined by Eq. (54); Φ_{max} is maximum limiting value of Φ
ϕ = fin efficiency [see Eq. (50)]; or angle [see Eq. (41)]

Subscripts

a = augmented
b = blackbody; based on bulk fluid temperature
c = convection; or critical; or cold (fluid)
e = equivalent; or environment
f = film; or fin
fc = finite cylinder
frs = finite rectangular solid
h = horizontal; or hot (fluid); or hydraulic
i = inlet; or inside; particular surface (radiation); based on maximum inside (envelope) diameter
ic = infinite cylinder
if = interface
is = infinite slab
iso = isothermal conditions
j = particular surface (radiation)
l = liquid
m = mean
max = maximum
min = minimum
o = outside; or outlet; or overall; or fin diameter
p = prime heat transfer surface
r = radiation; root (fin); or reduced
s = surface; secondary heat transfer surface; straight or plain; accounting for flow blockage of twisted tape
st = static (pressure)
t = temperature; or terminal temperature; or tip (fin)
v = vapor; or vertical
w = wall; or wafer
λ = monochromatic
∞ = bulk

CHAPTER 4

TWO-PHASE FLOW

Boiling 4.1
Condensing 4.9
Enhanced Surfaces 4.14
Symbols 4.14

TWO-PHASE flow is encountered extensively in the air-conditioning, heating, and refrigeration industries. Mixtures of liquid and vapor refrigerants exist in flooded coolers, direct expansion coolers, thermosiphon coolers, brazed and gasketed plate evaporators and condensers, tube-in-tube evaporators and condensers, as well as in air-cooled evaporators and condensers. A mixture of steam and water is found in the pipes of heating systems. Since the hydrodynamic and heat transfer aspects of two-phase flow are not as well understood as those of single-phase flow, no single set of correlations can be used to predict pressure drops or heat transfer rates. Instead, the correlations are for specific thermal and hydrodynamic operating conditions.

This chapter presents the basic principles of two-phase flow and provides information on the vast number of correlations that have been developed to predict heat transfer coefficients and pressure drops in these systems.

Breber *et al.* (1980) present a method of using a flow regime map to predict heat transfer coefficients for condensation of pure components in a horizontal tube.

BOILING

Commonly used refrigeration evaporators are: (1) flooded evaporators, where refrigerants boil outside or inside tubes with low fluid velocities; and (2) dry expansion shell-and-tube evaporators with boiling outside or inside tubes at substantial fluid velocities.

Flow of a two-phase mixture is characterized by various flow and thermal regimes, whether vaporization takes place under natural convection or in forced flow. As in single-phase flow systems, the heat transfer coefficient for a two-phase mixture depends on the flow regime. The thermodynamic and transport properties of the vapor and the liquid, the conditions (roughness and wettability) of the heating surface, and other parameters influence the heat transfer coefficients in different ways. Therefore, it is necessary to consider each flow and boiling regime separately to determine the coefficient.

Accurate data defining limits of regimes and determining the effects of various parameters are not available. The accuracy of previously proposed correlations to predict the heat transfer coefficient for two-phase flow is not known beyond the range of the test data.

Boiling and Pool Boiling in Natural Convection Systems

Regimes of boiling. The different regimes of pool boiling described by Farber and Scorah (1948) are illustrated in Figure 1. When the temperature of the heating surface is near the fluid saturation temperature, heat is transferred by convection currents to the free surface where evaporation occurs (Region I). Transition to nucleate boiling occurs when the surface temperature exceeds saturation by a few degrees (Region II).

In *nucleate boiling* (Region III), a thin layer of superheated liquid is formed adjacent to the heating surface. In this layer,

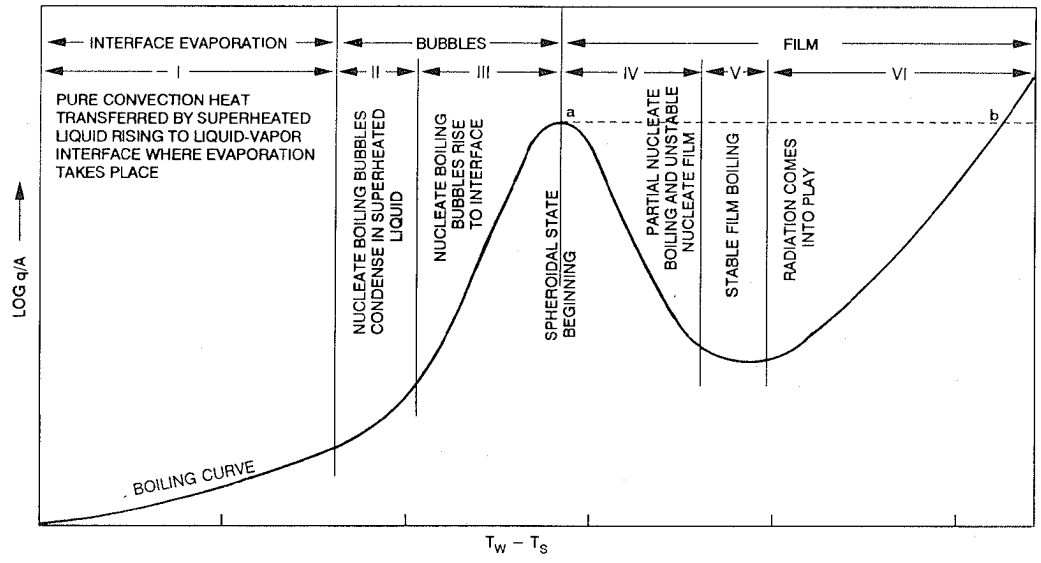

Fig. 1 Characteristic Boiling Curve

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

bubbles nucleate and grow from spots on the surface. The thermal resistance of the superheated liquid film is greatly reduced by bubble-induced agitation and vaporization. Increased wall temperature increases bubble population, causing a large increase in heat flux.

As heat flux or temperature difference increases further and as more vapor forms, the flow of the liquid toward the surface is interrupted and a vapor blanket forms. This gives the *maximum heat flux* or *peak heat flux* in nucleate boiling (point *a*, Figure 1). This flux is often termed the *burnout heat flux* because, for constant power-generating systems, an increase of heat flux beyond this point results in a jump of the heater temperature (to point *b*, Figure 1), often beyond the melting point of a metal heating surface.

In systems with controllable surface temperature, an increase beyond the temperature for peak heat flux causes a decrease of heat flux density. This is the *transitional boiling regime* (Region IV); liquid alternately falls onto the surface and is repulsed by an explosive burst of vapor.

At sufficiently high surface temperature, a stable vapor film forms at the heater surface; this is the *film boiling regime* (Regions V and VI). Since heat transfer is by conduction (and some radiation) across the vapor film, the heater temperature is much higher than for comparable heat flux densities in the nucleate boiling regime.

Free surface evaporation. In Region I, where surface temperature exceeds liquid saturation temperature by less than a few degrees, no bubbles form. Evaporation occurs at the free surface by convection of superheated liquid from the heated surface. Correlations of heat transfer coefficients for this region are similar to those for fluids under ordinary natural convection [Equations (1) through (4), Table 1].

Nucleate boiling. Much information is available on boiling heat transfer coefficients, but no universally reliable method is available for correlating this data. In the nucleate boiling regime, heat flux density is not a single, valued function of the temperature but depends also on the nucleating characteristics of the surface, as illustrated by Figure 2 (Berenson 1962).

The equations proposed for correlating nucleate boiling data can be put in a form that relates heat transfer coefficient h to temperature difference $(t_w - t_{sat})$:

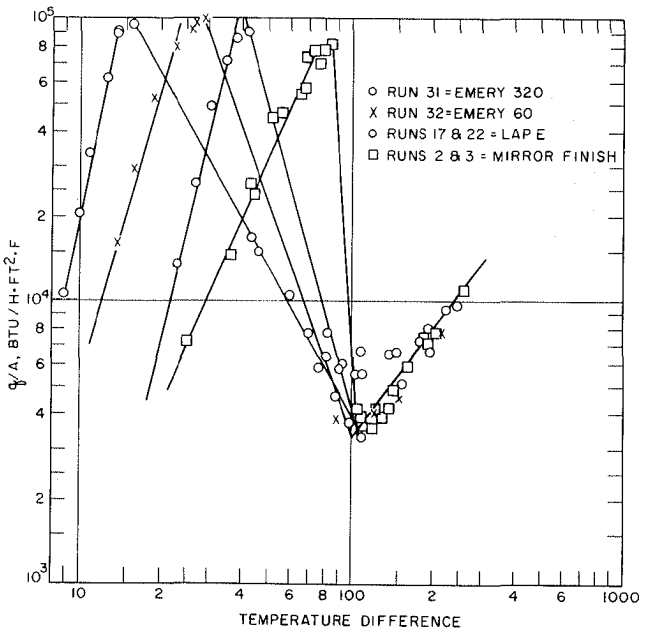

Fig. 2 Effect of Surface Roughness on Temperature in Pool Boiling of Pentane

$$h = \text{constant}\ (t_w - t_{sat})^a \quad (1)$$

Exponent a normally is between 1 and 3; the constant depends on the thermodynamic and transport properties of the vapor and the liquid. Nucleating characteristics of the surface (size distribution of surface cavities and wettability) affect the value of the multiplying constant and the value of the exponent a in Equation (1). For example, variations in exponent a from 1 to 25 can be produced by polishing the surface with different grades of emery paper.

A generalized correlation cannot be expected without considering the nucleating characteristics of the heating surface. A statistical analysis of data for 25 liquids by Hughmark (1962) shows that in a correlation not considering surface condition, deviations of more than 100% are common.

In the absence of quantitative nucleating characteristics, Rohsenow (1951) devised a test that evaluated surface effects at atmospheric pressure with a given surface-liquid combination. The effect of pressure can be sealed by using the dimensionless groups in Equation (5), Table 1. Values of the coefficient c_{sf} for some liquid-solid combinations found by Blatt and Adt (1963) are presented in Section II, Table 1.

The nomographs of Figures 3 and 4 (Stephan 1963) can be used to estimate the heat transfer coefficient for R-11, R-12, R-13, R-21, R-22, R-113, R-114, R-142, CO_2, CH_3Cl, NH_3, and SO_2 in nucleate boiling from a horizontal plate (Figure 3) and from the outside of a horizontal cylinder OD = 1.18 in. (Figure 4). Pressures range from 1 to 3 atm.

Stephan's correlation (1963a) is subject to the aforementioned limitations, since its form is that of Equation (1), with exponent a equal to 4 for horizontal plates, and 2.33 for horizontal cylinders. Data show variations of a from 2 to 25, depending on surface conditions. The nomographs of Figures 3 and 4 are based on experimental data and can be used for estimating the heat transfer coefficient within the range tested (Stephan 1963b).

Equation (6), Table 1, presents an extensively used correlation (Kutateladze 1963). It includes the effect of the diameter of the heating surface (Gilmour 1958), the last term on the right side. This equation predicts the heat transfer coefficients in nucleate boiling from horizontal and vertical plates and cylinders.

In addition to correlations dependent on thermodynamic and transport properties of the vapor and the liquid, Borishansky *et al.* (1962) and Lienhard and Schrock (1963) documented a correlating method based on the law of corresponding states. The properties can be expressed in terms of fundamental molecular parameters, leading to scaling criteria based on the reduced pressure, $p_r = p/p_c$, where p_c is the critical thermodynamic pressure for the coolant. An example of this method of correlation is shown in Figure 5. The reference pressure p^* was chosen as $p^* = 0.029\,p_c$. This correlation provides a simple method for scaling the effect of pressure if data are available for one pressure level. It also has an advantage if the thermodynamic and particularly the transport properties used in several equations in Table 1 are not accurately known. In its present form, this correlation gives a value of $a = 2.33$ for the exponent in Equation (1) and consequently should apply for typical aged metal surfaces.

There are explicit correlations for the heat transfer coefficient based on the law of corresponding states for various substances (Borishansky and Kosyrev 1966), specifically for halogenated refrigerants (Danilova 1965), including application to design of flooded evaporators (Starczewski 1965). Other investigations include the effect of oil on heat transfer from a flat plate during pool boiling (Stephan 1963); oil-R-12 mixtures boiling from a 0.55-in. OD horizontal tube (Tschernobyiski and Ratiani 1955); effect of oil on boiling R-12 from inside horizontal tubes (Breber *et al.* 1980, Worsoe-Schmidt 1959, Green and Furse 1963); R-11

Table 1 Equations for Boiling Heat Transfer

Description	Reference(s)	Equation
Free convection		
Free convection boiling, or boiling without bubbles for low Δt and Gr Pr $< 10^8$ (all properties to be based on liquid state)	Jakob (1949, 1957)	$\mathrm{Nu} = c(\mathrm{Gr})^m(\mathrm{Pr})^n$ (1)
Vertical submerged surface		$\mathrm{Nu} = 0.61\,(\mathrm{Gr})^{0.25}\,(\mathrm{Pr})^{0.25}$ (2)
Horizontal submerged surface		$\mathrm{Nu} = 0.16\,(\mathrm{Gr})^{1/3}\,(\mathrm{Pr})^{1/3}$ (3)
Simplified equation for water		$h \approx 80\,(\Delta t)^{1/3}$, where h is in Btu/h·ft²·°F, Δt in °F (4)
Nucleate boiling	Rohsenow (1951)	$(\mathrm{Nu})_b = (\mathrm{Re})_b^{2/3}(\mathrm{Pr})_l^{-0.7}/C_{sf}$ (5)
	Kutateladze (1963) Gilmour (1958)	$(\mathrm{Nu})_b = C_k\left[\frac{\rho_l}{\rho_v}\mathrm{Re}\right]_b^{0.7}(\mathrm{Pr})_l^{0.4}N_k^m\left[\frac{D_b}{D}\right]^n$ (6)
		where $(\mathrm{Nu})_b = hD_b/k_l$, $(\mathrm{Pr})_l = [\mu c_p/k]_l$
		$(\mathrm{Re})_b = q\,D_b/Ah_{fg}\,\mu_l$
		$D_b = \sqrt{\sigma_t/(\rho_l - \rho_v)g}$
		$N_k = p/[\sigma_t g(\rho_l - \rho_v)]^{0.5}$
	Blatt and Adt (1963)	C_{sf} = constant which depends on solid-liquid combination

Refrigerant	Stainless Steel	Copper
11	0.016	0.022
113	0.09	0.013

	Jakob (1949, 1957)	$C_k = 7.0 \times 10^{-4}$, $m = 0.7$, $n = 0$
		$C_k = 4.37 \times 10^{-3}$, $m = 0.95$, $n = 1/3$
Peak heat flux	Kutateladze (1951) Zuber *et al.* (1962)	$\frac{q/A}{\rho_v h_{fg}}\left[\frac{\rho^2 v}{\sigma_t g(\rho_l - \rho_v)}\right]^{0.25} = K$ (7)
		For many liquids, K varies from 0.12 to 0.16. Recommended average value is 0.13.
Minimum heat flux in film boiling horizontal plates	Zuber (1959)	$\frac{q/A}{\rho_v h_{fg}}\left[\frac{(\rho_l + \rho_v)}{\sigma_t g(\rho_l - \rho_v)}\right]^{0.25} = 0.09$ (8)
Horizontal cylinders	Lienhard and Wong (1963)	$\frac{q/A}{\rho_v h_{fg}}\left[\frac{(\rho_l + \rho_v)^2}{\sigma_t g(\rho_l - \rho_v)}\right]^{0.25} = 0.114\frac{\left[\frac{2\sigma_t}{g(\rho_l - \rho_v)D^2}\right]^{0.5}}{\left[1 + \frac{2\sigma_t}{g(\rho_l - \rho_v)D^2}\right]^{0.25}}$ (9)
Minimum temperature difference for film boiling from horizontal plate	Berenson (1961)	$(t_w - t_{sat}) = 0.127\frac{\rho_v h_{fg}}{k_v}\left[\frac{g(\rho_l - \rho_v)}{\rho_l + \rho_v}\right]^{2/3} \times \left[\frac{\sigma_t}{g(\rho_l - \rho_v)}\right]^{0.5}\left[\frac{\mu_v}{\rho_l - \rho_v}\right]^{1/3}$ (10)
Film boiling from horizontal plate	Berenson (1961)	$h = 0.425\left[\frac{k_v^3\rho_v h_{fg} g(\rho_l - \rho_v)}{\mu_v(t_w - t_{sat})\sqrt{\phi_t/g(\rho_l - \rho_v)}}\right]^{0.25}$ (11)
Film boiling from horizontal cylinders	Anderson *et al.* (1966)	$h = 0.62\left[\frac{k_v^3\rho_v g(\rho_l - \rho_v)h_{fg}}{D\mu_v(t_w - t_{sat})}\right]^{0.25}$ (12)
Effect of radiation	Anderson *et al.* (1966)	Substitute $h_{fg}' = h_{fg}\left[1 + 0.4c_p\frac{t_w - t_b}{h_{fg}}\right]$
Effect of surface tension and of pipe diameter	Breen and Westwater (1962)	$\Lambda/D < 0.8$: $h(\Lambda)^{0.25}/F = 0.60$ (13)
		$0.8 < \Lambda/D < 8$: $hD^{0.25}/F = 0.62$ (14)
		$8 < \Lambda/D$: $h(\Lambda)^{0.25}/F = 0.016\ (\Lambda/D)^{0.83}$ (15)
		where $\Lambda = 2\pi\left[\frac{\sigma_t}{g(\rho_l - \rho_v)}\right]^{0.25}$
		$F = \left[\frac{\rho_v h_{fg} g(\rho_l - \rho_v)k_v^3}{\mu_v(t_w - t_{sat})}\right]^{0.25}$
Turbulent film	Frederking and Clark (1962)	$\mathrm{Nu} = 0.15\,(\mathrm{Ra})^{1/3}$ for $\mathrm{Ra} > 5 \times 10^7$ (16)
		$\mathrm{Ra} = \left[\frac{D^3 g(\rho_l - \rho_v)}{\nu_v^2\rho_v}\left(\frac{c_p\mu}{k}\right)_v\left(\frac{h_{fg}}{c_p(t_w - t_{sat})} + 0.4\right)\frac{a}{g}\right]^{1/3}$
		a = local acceleration

and R-12 boiling over a flat horizontal copper surface (Furse 1965); and R-11 and R-113 with oil content to 10% boiling from commercial copper tubing (Dougherty and Sauer 1974).

Maximum Heat Flux and Film Boiling

Maximum heat flux and the film boiling region are not as strongly affected by conditions of the heating surface as the heat flux in the nucleate boiling region, making analysis of peak heat flux and of film boiling more tractable.

When peak heat flux is assumed to be a hydrodynamic instability phenomenon, a simple relation, Equation (7), Table 1, can be derived to predict this flux for pure, wetting liquids (Kutateladze 1951, Zuber *et al.* 1962). The dimensionless constant varies from approximately 0.12 to 0.16 for a large variety of liquids. The effect of wettability is still in question. Van Stralen (1959) found that for liquid mixtures, peak heat flux is a function of the concentration.

The minimum heat flux density in film boiling from a horizontal surface and a horizontal cylinder can be predicted by Equations (8) and (9), Table 1. The numerical factors 0.09 and 0.114 were adjusted to fit experimental data; values predicted by two analyses were approximately 30% higher. Equation (10), Table 1, predicts the temperature difference at minimum heat flux of film boiling.

The heat transfer coefficient in film boiling from a horizontal surface can be predicted by Equation (11), Table 1; from a horizontal cylinder by Equation (12), Table 1 (Bromley 1950), which has been generalized to include the effect of surface tension and cylinder diameter, as shown in Equations (13), (14), and (15), Table 1 (Breen and Westwater 1962).

Frederking and Clark (1962) found that for turbulent film boiling, Equation (16), Table 1, agrees with data from experiments at reduced gravity (Rohsenow 1963, Westwater 1963, Kutateladze 1963, Jakob 1949, 1957).

Flooded Evaporators

Equations in Table 1 merely approximate heat transfer rates in flooded evaporators. One reason is that vapor entering the evaporator, combined with vapor generated within the evaporator, can produce significant forced convection effects superimposed on those caused by nucleation. Nonuniform distribution of the two-phase, vapor-liquid flow within the tube bundle of shell-and-tube evaporators or the tubes of vertical-tube flooded evaporators, is also important.

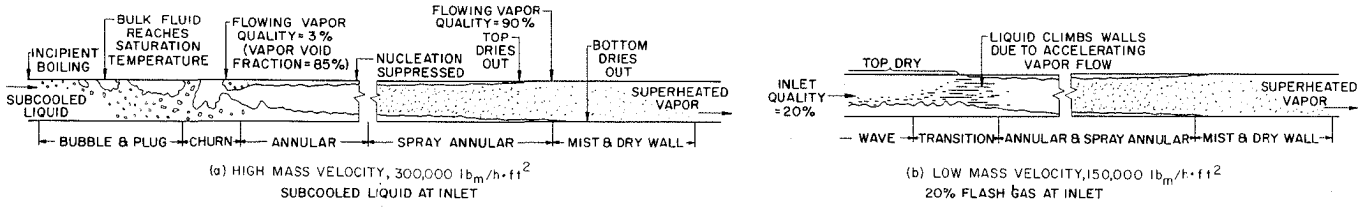
Myers and Katz (1952) investigated the effect of vapor generated by the bottom rows of a tube bundle on the heat transfer coefficient for the upper rows. Improvement in coefficients for the upper tube rows is greatest at low temperature differences where nucleation effects are less pronounced. Hofmann (1956) summarizes other data for flooded tube bundles.

Typical performance of vertical tube natural circulation evaporators, based on data for water, is shown in Figure 6 (Perry 1950). Low coefficients are at low liquid levels because insufficient liquid covers the heating surface. The lower coefficient at high levels is the result of an adverse effect of hydrostatic head on temperature difference and circulation rate. Perry (1950) noted similar effects in horizontal shell-and-tube evaporators.

Forced Convection Evaporation in Tubes

Flow mechanics. When a mixture of liquid and vapor flows inside a tube, a number of flow patterns occur, depending on the mass fraction of liquid, the fluid properties of each phase, and the flow rate. In an evaporator tube, the mass fraction of liquid decreases along the circuit length resulting in a series of changing gas-liquid flow patterns. If the fluid enters as a subcooled liquid, the first indications of vapor generation are bubbles forming at the heated tube wall (nucleation). Subsequently, bubble, plug, churn (or semiannular), annular, spray-annular, and mist flows can occur as the vapor content increases. Idealized flow patterns are illustrated in Figure 7a for a horizontal tube evaporator.

Since nucleation occurs at the heated surface in a thin sublayer of superheated liquid, boiling in forced convection may begin while the bulk of the liquid is subcooled. Depending on the nature of the fluid and the amount of subcooling, the bubbles formed can collapse, or continue to grow and coalesce (Figure 7a), as Gouse and Coumou (1965) observed for R-113. Bergles and Rohsenow (1964) developed a method to determine the point of incipient surface boiling.



Constant heat flux; tube diameter approximately 0.5 in.

Fig. 7 Flow Regimes in Horizontal Tube Evaporator

After nucleation begins, bubbles quickly agglomerate to form vapor slugs at the center of a vertical tube, or, as shown in Figure 7a, vapor plugs form along the top surface of a horizontal tube. At the point where the bulk of the fluid reaches saturation temperature, corresponding to local static pressure, there will be up to 1% vapor quality because of the preceding surface boiling (Guerrieri and Talby 1956).

Further coalescence of vapor bubbles and plugs results in churn or semiannular flow. If the fluid velocity is high enough, a continuous vapor core surrounded by a liquid annulus at the tube wall soon forms. This annular flow occurs when the ratio of the tube cross section filled with vapor to the total cross section is approximately 85%. With common refrigerants, this equals a vapor quality of about 3 to 5%. The usual flowing vapor quality or vapor fraction is referred to throughout this discussion. Static vapor quality is smaller, since the vapor in the core flows at a higher average velocity than the liquid at the walls (see Chapter 2).

If two-phase mass velocity is high, greater than 150,000 $lb_m/h \cdot ft^2$ for a 0.5-in. tube, annular flow with small drops of entrained liquid in the vapor core (spray) can persist over a vapor quality range from a few percentage points to more than 90%. Refrigerant evaporators are fed from an expansion device at vapor qualities of approximately 20%, so that annular and spray-annular flow predominate in most tube lengths. In a vertical tube, the liquid annulus is distributed uniformly over the periphery, but it is somewhat asymmetric in a horizontal tube (Figure 7a). As vapor quality reaches about 90%, the surface dries out, although there are still entrained droplets of liquid in the vapor (mist). Chaddock and Noerager (1966) found that in a horizontal tube, dryout occurs first at the top of the tube, and later at the bottom (Figure 7a).

If two-phase mass velocity is low, less than 150,000 $lb_m/h \cdot ft^2$ for a 0.5-in. horizontal tube, liquid occupies only the lower cross section of the tube. This causes a wavy type of flow at vapor qualities above about 5%. As the vapor accelerates with increasing evaporation, the interface is disturbed sufficiently to develop annular flow (Figure 7b). Liquid slugging can be superimposed on the flow configurations illustrated; the liquid forms a continuous, or nearly continuous, sheet over the tube cross section. The slugs move rapidly and at irregular intervals.

Heat transfer. It is difficult to develop a single relation to describe the heat transfer performance for evaporation in a tube over the full quality range. For refrigerant evaporators with several percentage points of flash gas at entrance, it is less difficult, since annular flow occurs in most of the tube length. The reported data are accurate only within geometry, flow, and refrigerant conditions tested; therefore, a large number of methods for calculating heat transfer coefficients for evaporation in tubes are presented in Table 2 (also see Figures 8 through 11).

Figure 8 gives data obtained for R-12 evaporating in a 0.575-in. copper tube (Ashley 1942). The curves for other tube diameters

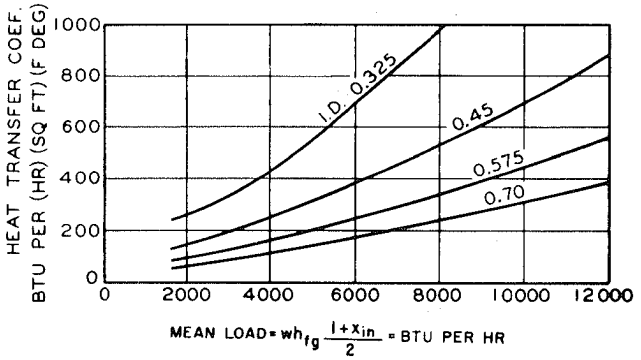


Fig. 8 Boiling Heat Transfer Coefficients for R-12 Inside Horizontal Tubes

are approximations based on an assumed dependence, as in Table 2. Heat transfer coefficient dependence can be understood better from the data in Figure 9 (Gouse and Coumou 1965). At low mass velocities, below 150,000 $lb_m/h \cdot ft^2$, the wavy flow regime of Figure 7b probably exists, and the heat transfer coefficient is nearly constant along the tube length, dropping at the tube exit as complete vaporization occurs. At higher mass velocities, the

Equations	Comments and References
HORIZONTAL TUBES	
Graphical presentation in Figure 8 h versus q_m where $q_m = wh_{fg}(1 + x)/2$	Average coefficients for complete evaporation of R-12 at 40°F in a 0.575-in. ID copper tube, 33 ft long; the curves for other diameters in Figure 4 are based on the assumption that h varies inversely as the square of the tube diameter (Ashley 1942).
Graphical presentation in Figure 9 h versus x_2 where x_2 = leaving vapor fraction	Average coefficients for R-22 evaporating at 40°F in a 0.665-in. ID copper tube, 7.5 ft long. Vapor fraction varied from 20% to 100%. Average coefficients plotted are for vapor fraction changes of 0.20 (or 0.10). For average coefficients (at the same heat flux) over larger vapor fraction ranges, the curves can be integrated (Anderson *et al.* 1966).
$h = c_1\left(\frac{k_l}{d}\right)\left[\left(\frac{GD}{\mu_l}\right)^2\left(\frac{J\Delta x h_{fg}}{L}\right)\right]^n$ (1) *where* $c_1 = 0.0009$ and $n = 0.5$ for exit qualities ≤ 90%; and $c_1 = 0.0082$ and $n = 0.4$ for 11°F superheat at exit	Average coefficients for R-12 and R-22 evaporating in copper tubes of 0.472 and 0.709-in. ID, from 13.4 to 31.2 ft long, and at evaporating temperatures from −4 to 32°F. Vapor fraction varied from 0.15 to 11°F superheat. Note that the term $J\Delta x h_{fg}/L$ is not dimensionless, but has the units of pound force per pound mass (Pierre 1955, 1957).
Equation (1) of Pierre with $c_1 = 0.0225$ and $n = 0.375$	Average coefficients for R-22 evaporating at temperatures from 40 to 80°F in a 0.343-in. ID tube, 8 ft long. Coefficients were determined for approximately 15% vapor quality changes. The range investigated was $x = 0.20$ to superheat (Altman *et al.* 1960b).
$h = c_2 h_l\left(\frac{1 + x}{1 - x}\right)^{1.16}\left(\frac{q}{Gh_{fg}}\right)^{0.1}$ (2) *where* $c_2 = 6.59$	Local coefficients for R-12 and R-22 evaporating in a 0.732-in. ID tube 1 ft long at saturation temperatures from 75 to 90°F. Location of transition from annular to mist flow is established, and a heat transfer equation for the mist flow regime is presented (Lavin and Young 1964).
$h_l = \frac{0.023\,k_l}{d}\left[\frac{DG(1 - x)}{\mu_l}\right]^{0.8}(\mathrm{Pr})_l^{0.4}$ (3)	
$h = 1.85\,h_L[B_o \times 10^4 + (1/X_{tt})^{0.67}]^{0.6}$ (4) *where* $B_o = q/Gh_{fg}$ (5) $h_L = \frac{0.023k_l}{d}\left(\frac{DG}{\mu_l}\right)^{0.8}(\mathrm{Pr})_l^{0.4}$ (6) $X_{tt} = \left(\frac{1 - x}{x}\right)^{0.9}\left(\frac{\rho_v}{\rho_l}\right)^{0.5}\left(\frac{\mu_l}{\mu_v}\right)^{0.1}$ (7)	Local coefficients for R-12 evaporating in a 0.460-in. ID stainless steel tube with a uniform wall heat flux (electric heating) over a length of 6.344 ft, and an evaporating temperature of 53°F. Vapor fraction range was 0.20 to 0.88. Equation (4) is a modified form of the Schrock and Grossman equation for vertical tube evaporation [Equation (10)] (Chaddock and Noerager 1966).
Best agreement was with Equation (11) for vertical tubes.	Local coefficients for R-113 evaporating in a 0.430-in. ID transparent tube with a uniform wall heat flux over a length of 12.5 ft; evaporating temperature approximately 120°F. Report includes photographs of subcooled surface boiling, bubble, plug, and annular flow evaporation regimes (Gouse and Coumou 1965).
VERTICAL TUBES	
$h = 3.4h_l(1/X_{tt})^{0.45}$ (8) $h = 3.5h_L(1/X_{tt})^{0.5}$ (9) *where* h_l is from (3), X_{tt} from (7), h_L from (6)	Equations (8) and (9) were fitted to experimental data for vertical upflow in tubes. Both relate to forced convection evaporation regions where nucleate boiling is suppressed (Guerrieri and Talty 1956, Dengler and Addoms 1956). (A multiplying factor is recommended when nucleation is present.)
$h = 0.74h_L[B_o \times 10^4 + (1/X_{tt})^{0.67}]$ (10) *where* B_o is from (5), h_L from (6), X_{tt} from (7)	Local coefficients for water in vertical upflow in tubes with diameters from 0.1162 to 0.4317 in. and lengths of 15 to 40 in. The boiling number B_o accounts for nucleation effects, and the Martinelli parameter x_{tt} for forced convection effects (Schrock and Grossman 1962).
$h = h_{mic} + h_{mac}$ (11) *where* $h_{mac} = h_l F_c$ (12) $h_{mic} = 0.00122\,(S_c)(E)(\Delta t)^{0.24}(\Delta P)^{0.75}$ (13) F_c and S_c from Figures 10 and 11	Chen developed this correlation reasoning that the nucleation transfer mechanism (represented by h_{mic}) and the convective transfer mechanism (represented by h_{mac}) are additive. h_{mac} is expressed as a function of the two-phase Reynolds number after Martinelli, and h_{mic} is obtained from the nucleate boiling correlation of Forster and Zuber (1955). S_c is a suppression factor for nucleate boiling (Chen 1963).
$E = \frac{k_l^{0.79}(c_p)_l^{0.45}\rho_l^{0.49}g_c^{0.25}}{\sigma_l^{0.50}\mu_l^{0.29}h_{fg}^{0.24}\rho_v^{0.24}}$ (14) Equation (2) with $c_2 = 3.79$	See comments for Equation (2). Note the superior performance of the horizontal versus vertical configuration ($c_2 = 6.59$ versus 3.79) from this investigation which used the same apparatus and test techniques for both orientations (Lavin and Young 1964).

Note: Except for dimensionless equations, units are lb_m, h, ft, °F, and Btu.

For $\frac{DG_l}{\mu_l} > 5000\,\frac{DG_v}{\mu_l}\left(\frac{\rho_l}{\rho_v}\right)^{0.5} > 20{,}000$	Ackers *et al.* (1959)	$\frac{hD}{k_l} = 0.026\left(\frac{c_p\mu_l}{k_l}\right)^{1/3}\left(\frac{DG_E}{\mu_l}\right)^{0.8}$ where $G_E = G_v(\rho_l/\rho_v)^{0.5} + G_l$	(13)
	Altman *et al.* (1960a)	$h = 0.057\left(\frac{c_pk_f\rho_f}{\mu_f}\right)^{0.5}F^{0.5}$ where $F = \Delta p_{TPF}\left(\frac{g_oD}{4L}\right)$	(14)
	Forster and Zuber (1955)	Δp_{TPF} = frictional two-phase pressure drop	

Note: Equations (1) through (10) and Equation (14) are dimensional with units of Btu, h, ft, °F, and lb_m.

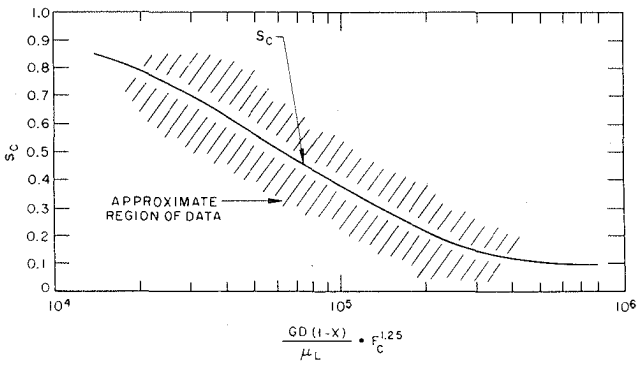

Fig. 11 Suppression Factor S_c

flow pattern is usually annular, and the coefficient increases as vapor accelerates. As the surface dries at a 90% vapor quality, the coefficient drops sharply.

Equation (1), Table 2, is recommended for broadest application to refrigerant evaporation in tubes (Pierre 1955, 1957). It fits a wide range of R-12 and R-22 data.

Equations (2), (10), and (11) in Table 2 include terms for velocity effect (convection) and heat flux (nucleation), and produce local heat transfer coefficients as a function of the local vapor quality x and heat transfer rate q. Local rather than average coefficients are used for accurate design.

The effect of oil on forced convection evaporation has not been clearly determined. Increases occur in the *average* heat transfer coefficient for R-12 up to 10% oil by weight, with a maximum of about 4% (Green and Furse 1963, Worsoe-Schmidt 1960). Oil quantities greater than 10% cause reduction in heat transfer. Oil can increase the pressure drop, offsetting possible gains in the heat transfer coefficient.

CONDENSING

Condensation occurs when a saturated vapor contacts a surface at a lower temperature than the saturation temperature of the vapor. The vapor loses its latent heat of vaporization and condenses on the surface.

Film condensation occurs in most applications. The liquid condensate covers the condensing surface with a continuous film and flows off the surface by gravity. *Dropwise condensation* is seen as steam on highly polished surfaces or on surfaces contaminated with fatty acids.

The rate of heat flow depends on the condensate film thickness, which depends on the rate of vapor condensation and the rate of condensate removal. At high reduced pressures, the heat transfer coefficients for dropwise condensation, at the same surface loading, are higher than those available in the presence of film condensation. At low reduced pressures, the reverse is true. For example, there is a reduction of 6 to 1 in the dropwise condensation coefficient of steam when saturation pressure is decreased from 0.9 to 0.16 atm. One method for correlating the dropwise condensation heat transfer coefficient employs nondimensional parameters, including the effect of surface tension gradient, temperature difference, and fluid properties.

When condensation occurs on horizontal tubes and short vertical plates, the condensate film motion is laminar. On vertical tubes and long vertical plates, the film can become turbulent. Grober *et al.* (1961) suggest using a Reynolds number of 1600 as the critical point where the flow pattern changes from laminar to turbulent. This Reynolds number is based on condensate flow rate divided by the breadth of the condensing surface. For a vertical tube, the breadth is the circumference of the tube; for a horizontal tube, the breadth is twice the length of the tube. The Reynolds number $= 4w/\mu_f$, where w is the mass flow of condensate per unit of breadth, and μ_f is the viscosity of the condensate at the film temperature t_f. In practice, condensation is usually laminar in shell-and-tube condensers with the vapor outside horizontal tubes.

Vapor velocity also affects the condensing coefficient. When this is small, condensate flows primarily by gravity and is resisted by the viscosity of the liquid. When vapor velocity is high relative to the condensate film, there is appreciable drag at the vapor-liquid interface. The thickness of the condensate film, and hence the heat transfer coefficient, is affected. When vapor flow is upward, a retarding force is added to the viscous shear, increasing the film thickness. When vapor flow is downward, the film thickness decreases and the heat transfer coefficient increases. For condensation inside horizontal tubes, the force of the vapor velocity causes the condensate to flow. When the vapor velocity is high, the transition from laminar to turbulent flow occurs at lower Reynolds numbers.

When *superheated* vapor is condensed, the heat transfer coefficient depends on the surface temperature. When the surface temperature is *below* saturation temperature, there is little error if the value of h for condensation of saturated vapor is used with the difference between the *saturation* temperature and the surface temperature (McAdams 1954). If the surface temperature is *above* the saturation temperature, there is no condensation and the equations for gas convection apply.

Correlation equations for condensing heat transfer are given in Table 3. Factors F_1 and F_2, which depend only on the physical properties of the refrigerant and which occur often in these equations, have been computed for some commonly used refrigerants in Table 4. Refrigerant properties used in the calculations may be found in Chapter 16.

Table 4 Values of Condensing Coefficient Factors for Different Refrigerants (from Chapter 16)

Refrigerant	Film Temperature, °F $t_f = t_{sat} - 0.75\,(\Delta t)$	F_1	F_2
Refrigerant 11	75	154	822
	100	153	815
	125	151	803
Refrigerant 12	75	133	672
	100	122	608
	125	112	538
Refrigerant 22	75	153	822
	100	144	755
	125	132	675
Sulfur Dioxide	75	290	1920
	100	299	2000
	125	318	2170
Ammonia	75	409	3040
	100	408	3035
	125	408	3030
Propane	75	159	850
	100	157	845
	125	154	836
Butane	75	156	840
	100	156	843
	125	157	845

$$F_1 = \left(\frac{k_f^3 \rho_f^2 g}{\mu f}\right)^{0.25} \qquad \text{Units} = \left(\frac{(\text{Btu})^3(\text{lb}_m)}{(\text{h})^4(\text{ft})^7(^\circ\text{F})^3}\right]^{0.25}$$

$$F_2 = \left(\frac{k_f^3 \rho_f^2 g}{\mu f}\right)^{1/3} \qquad \text{Units} = \left(\frac{(\text{Btu})^3(\text{lb}_m)}{(\text{h})^4(\text{ft})^7(^\circ\text{F})^3}\right)^{1/3}$$

In some cases, the equations are given in two forms: one is convenient when the amount of refrigerant to be condensed or the condensing load is known; the second is useful when the difference between the vapor temperature and the condensing surface temperature is known.

Condensation Outside Vertical Tubes

For film-type condensation outside vertical tubes and on vertical surfaces, Equations (1) and (2), Table 3, are recommended when $4w/\mu_f$ is less than 1800 (McAdams 1954). Fluid properties are evaluated at the mean film temperature. When $4w/\mu_f$ is greater than 1800 (tall vertical plates or tubes), use Equations (3) or (4), Table 3. Equations (2) and (4), Table 3, are plotted in Figure 12. The theoretical curve for laminar film-type condensation is shown for comparison. A semitheoretical relationship for turbulent film-type condensation is also shown for Pr values of 1.0 and 5.0 (Colburn 1933-34).

Condensation Outside Horizontal Tubes

For a bank of N tubes, Nusselt's equations, increased by 10% (Jakob 1949, 1957), are given in Equations (5) and (6), Table 3. Experiments by Short and Brown (1951) with R-11 suggest that drops of condensation falling from row to row cause local turbulence and increase heat transfer.

For condensation outside horizontal finned tubes, Equation (7), Table 3, is used for liquids that drain readily from the surface (Beatty and Katz 1948). For condensing steam outside finned tubes, where liquid is retained in the spaces between the tubes, coefficients substantially lower than those given by Equation (7), Table 3, were reported. For additional data on condensation outside finned tubes, see Katz *et al.* (1947).

Simplified Equations for Steam

For film-type steam condensation at atmospheric pressure and film temperature drops of 10 to 150 °F, McAdams (1954) recommends Equations (8) and (9), Table 3.

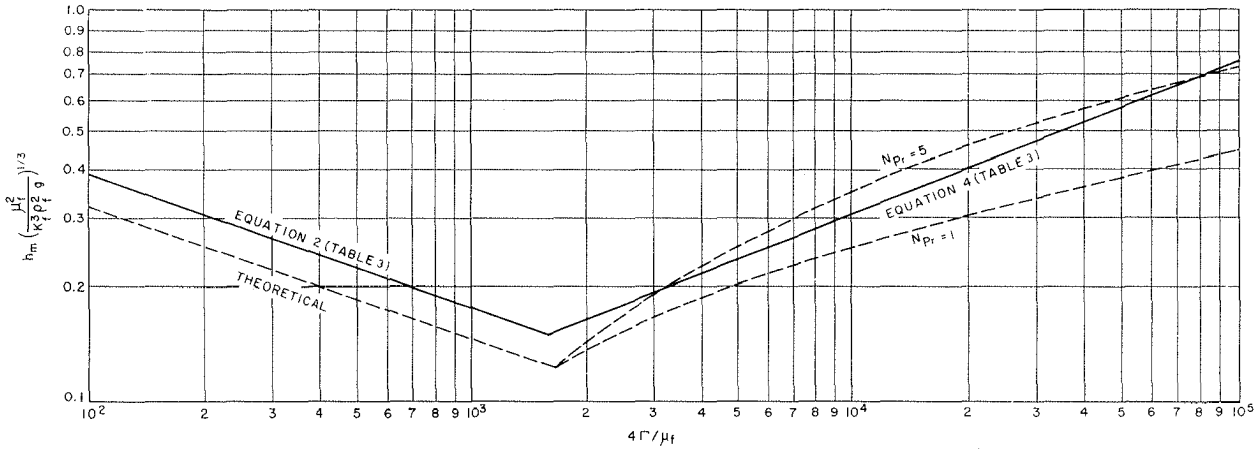

Fig. 12 Film-Type Condensation

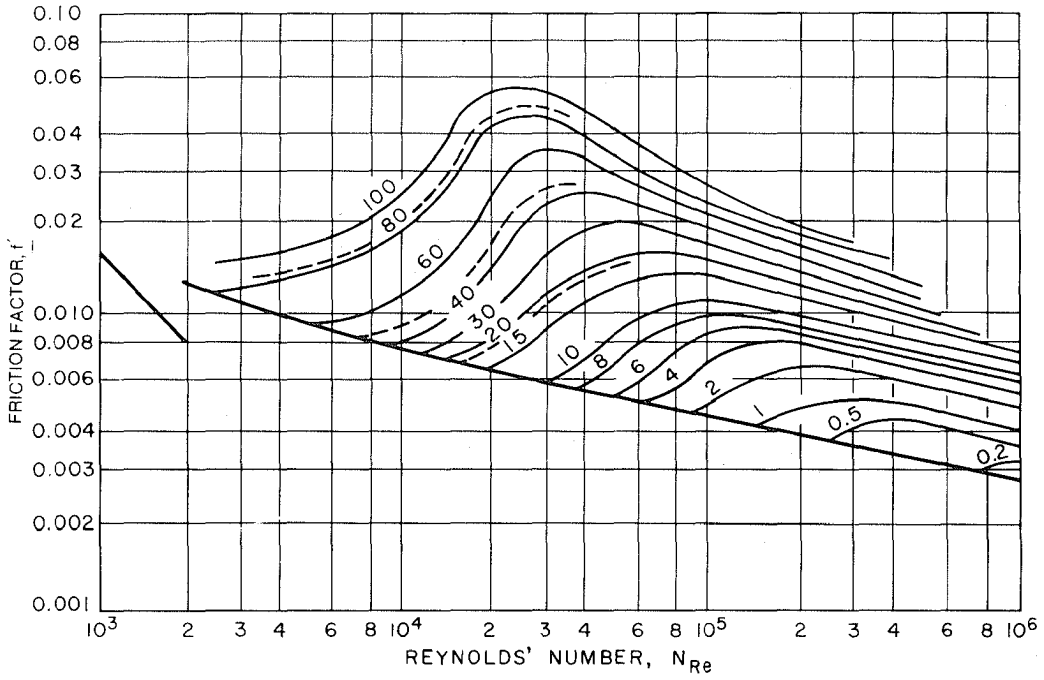

Curve parameter = $\Gamma/\rho s$, where Γ = liquid flow rate, ρ = liquid density, and s = surface tension of liquid relative to water; values of gas velocity used in calculating f and Re are calculated as though no liquid was present.

Fig. 13 Friction Factors for Gas Flow Inside Pipes with Wetted Walls

Condensation Inside Vertical Tubes

Condensation inside tubes is generally affected by appreciable vapor velocity. The measured heat transfer coefficients are as much as 10 times those predicted by Equation (4), Table 3. For vertical tubes, Jakob (1949, 1957) gives theoretical derivations for upward and downward vapor flow. For downward vapor flow, Carpenter and Colburn (1949) suggest Equation (10), Table 3. The friction factor f' for vapor in a pipe containing condensate should be taken from Figure 13.

Condensation Inside Horizontal Tubes

For condensation inside horizontal tubes (as in air-cooled condensers, evaporative condensers, and some shell-and-tube condensers), the vapor velocity and resulting shear at the vapor-liquid interface are major factors in analyzing heat transfer. Hoogendoorn (1959) identified seven types of two-phase flow patterns. For semistratified and laminar annular flow, use Equations (11) and (12), Table 3 (Ackers and Rosson 1960). Ackers *et al.* (1959) recommend Equation (13), Table 3, for turbulent annular flow (vapor Reynolds number greater than 20,000, and liquid Reynolds number greater than 5000). Equation (14), Table 3, correlates the local heat transfer coefficients for R-22 condensing inside pipes (Altman *et al.* 1960b); R-22 and several other fluids take the same form. The two-phase pressure drop in Equation (14) is determined by the method proposed by Martinelli and Nelson (1948); see also Altman *et al.* (1960a). A method for using a flow regime map to predict the heat transfer coefficient for condensation of pure components in a horizontal tube is presented in Breber *et al.* (1980).

Noncondensable Gases

Condensation heat transfer rates reduce drastically if one or more noncondensable gases are present in the condensing vapor/gas mixture. The decrease in the heat transfer coefficient is approximately linear with the weight fraction of the noncondensable gas present. The condensable component is termed *vapor*, and the noncondensable component, *gas*. In a steam chest with 2.89% air by volume, Othmer (1929) found that the heat transfer coefficient dropped from about 2000 to about 600 Btu/h·ft²·°F. Consider a surface cooled to some temperature t_s below the saturation temperature of the vapor (Figure 14). Accumulated condensate falls or is driven across the condenser surface. At a finite heat transfer rate, a temperature profile develops across the condensate that can be estimated from Table 3. Therefore, the interface of the condensate is at a temperature $t_{if} > t_s$. In the absence of gas, the interface temperature is the vapor saturation temperature at the pressure of the condenser.

The presence of noncondensable gas lowers the vapor partial pressure and, hence, the saturation temperature of the vapor in equilibrium with the condensate. Further, the movement of the vapor toward the cooled surface implies similar bulk motion of the gas. At the condensing interface, the vapor is condensed at temperature t_{if} and is then swept out of the system as a liquid. The gas concentration rises to ultimately diffuse away from the cooled surface at the same rate as it is convected toward the surface (Figure 14). If gas (mole fraction) concentration is Y_g and total pressure of the system is p, the partial pressure of the bulk gas is:

$$p_{g\infty} = Y_{g\infty} p \tag{2}$$

The partial pressure of the bulk vapor is:

$$p_{v\infty} = (1 - Y_{g\infty})p = Y_{v\infty} p \tag{3}$$

As opposing fluxes of convection and diffusion of the gas increase, the partial pressure of gas at the condensing interface is $p_{gif} > p_{g\infty}$. By Dalton's law, assuming isobaric condition:

$$p_{gif} + p_{vif} = p \tag{4}$$

Hence, $p_{vif} < p_{v\infty}$.

Sparrow *et al.* (1967) noted that thermodynamic equilibrium exists at the interface, except in the case of very low pressures or liquid metal condensation, so that:

$$p_{vif} = p_{sat}\,(t_{if}) \tag{5}$$

where $p_{sat}\,(t)$ is the saturation pressure of the vapor at temperature t. The available Δt for condensation across the condensate film is reduced from $(t_\infty - t_s)$ to $(t_{if} - t_s)$, where t_∞ is the bulk temperature of the condensing vapor-gas mixture, caused by the additional noncondensable resistance.

The equations in Table 3 are still valid for the condensate resistance, but the interface temperature t_{if} must be found. The noncondensable resistance, which accounts for the temperature difference $(t_\infty - t_{if})$, depends on the heat flux (through the convecting flow to the interface) and the diffusion of gas away from the interface.

In simple cases, Sparrow *et al.* (1967), Rose (1969), and Sparrow and Lin (1964) found solutions to the combined energy, diffusion, and momentum problem of noncondensables, but they are cumbersome.

A general method given by Colburn and Hougen (1934) can be used over a wide range if correct expressions are provided for the rate equations—add the contributions of the sensible heat transport through the noncondensable gas film and the latent heat transport via condensation:

$$h_g(t_\infty - t_{if}) + KM_v h_{fv}(p_{v\infty} - p_{vif}) = h(t_{if} - t_s) = U(t_{if} - t_c) \tag{6}$$

where h is from the appropriate equation in Table 3.

The value of the heat transfer coefficient for the stagnant gas depends on the geometry and flow conditions. For flow parallel to a condenser tube, for example:

$$j = \frac{h_g}{(c_p)_g G}\left(\frac{(c_p)_g \mu_{gv}}{K_g}\right)^{2/3} \tag{7}$$

where j is a known function of $\mathrm{Re} = GD/\mu_{gv}$.

The mass transfer coefficient K is:

$$\frac{K}{M_m}\left[\frac{p_{g\infty} - p_{gif}}{\ln(p_{g\infty}/p_{gif})}\right]\left(\frac{\mu_{gv}}{\rho_g D}\right)^{2/3} = j \tag{8}$$

The calculation method requires substitution of Equation (8) into Equation (6). For a given flow condition, G, Re, j, M_m, $p_{g\infty}$, h_g, and h (or U) are known. Assume values of t_{if}; calculate p_{sat} $(t_{if}) = p_{vif}$ and hence p_{gif}. If t_s is not known, use the overall coef-

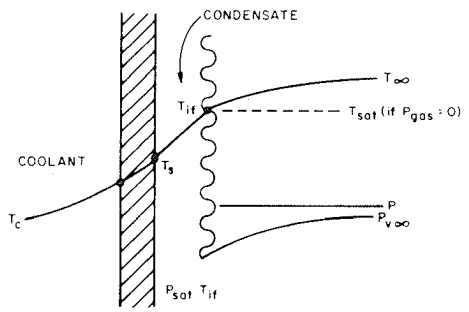

Fig. 14 Origin of Noncondensable Resistance

ficient U to the coolant at t_c in place of h and t_s in Equation (6). For either case, at each location in the condenser, iterate Equation (6) until it balances, giving the condensing interface temperature and, hence, the thermal load to that point (Colburn and Hougen 1934, Colburn 1951).

Other Impurities

Vapor entering the condenser often contains a small percentage of impurities such as oil. Oil forms a film on the condensing surfaces, creating additional resistance to heat transfer. Some allowance should be made for this, especially in the absence of an oil separator or when the discharge line from the compressor to the condenser is short.

Pressure Drop

Total pressure drop for two-phase flow in tubes consists of friction, acceleration, and gravitational components. It is necessary to know the *void fraction* (the ratio of gas flow area to total flow area) to compute the acceleration and gravitational components. To compute the frictional component or pressure drop, either the *two-phase friction factor* or the *two-phase frictional multiplier* must be known.

The homogeneous model provides a simple method for computing the acceleration and gravitational components of pressure drop. The homogeneous model assumes that the flow can be characterized by average fluid properties and that the velocities of the liquid and vapor phases are equal (Collier 1972, Wallis 1969).

Martinelli and Nelson (1948) developed a method for predicting the void fraction and two-phase frictional multiplier to use with a separated flow model. This method predicts the pressure drops of boiling refrigerants reasonably well. Other methods of computing the void fraction and two-phase frictional multiplier used in a separated flow model are given in Collier (1972) and Wallis (1969).

The general nature of annular gas-liquid flow in vertical, and to some extent horizontal, pipe is indicated (Wallis 1970) in Figure 15, which plots effective gas friction factor versus the liquid fraction $(1 - a)$. Here a is the void fraction, or fraction of the pipe cross section taken up by the gas or vapor.

The effective gas friction factor is defined as:

$$f_{eff} = \left[\frac{a^{5/2}D}{2\rho_g(4Q_g/\pi D^2)^2}\right]\left(-\frac{dp}{ds}\right) \tag{9}$$

where D is the pipe diameter, ρ_g the gas density, and Q_g the gas volume flow rate. The friction factor of gas flowing by itself in the pipe (presumed smooth) is denoted by f_g. Wallis' analysis of the flow occurrences is based on interfacial friction between the gas and liquid. The wavy film corresponds to a conduit of relative roughness (ϵ/D), about four times the liquid film thickness. Thus, the pressure drop relation of vertical flow is:

$$\left(-\frac{dp}{ds} + \rho_g g\right) = 0.01\,(\rho_g/D^5)(4Q_g/\pi)^2\,\frac{1+\,75(1-a)}{a^{5/2}} \tag{10}$$

This corresponds to the Martinelli-type analysis with:

$$f_{two\text{-}phase} = \phi_g^2 f_g$$

when

$$\phi_g^2 = \frac{1\,+\,75(1-\mathrm{a})}{a^{5/2}} \tag{11}$$

where the friction factor f_g (of the gas alone) is taken as 0.02, an appropriate turbulent flow value. This calculation can be modified for more detailed consideration of factors, such as Reynolds number variation in friction, gas compressibility, and entrainment (Wallis 1970).

In two-phase flow inside horizontal tubes, the pressure gradient is written as the sum of frictional and momentum terms. Thus:

$$\left(\frac{dp}{dz}\right) = \left(\frac{dp}{dz}\right)_f + \left(\frac{dp}{dz}\right)_m \tag{12}$$

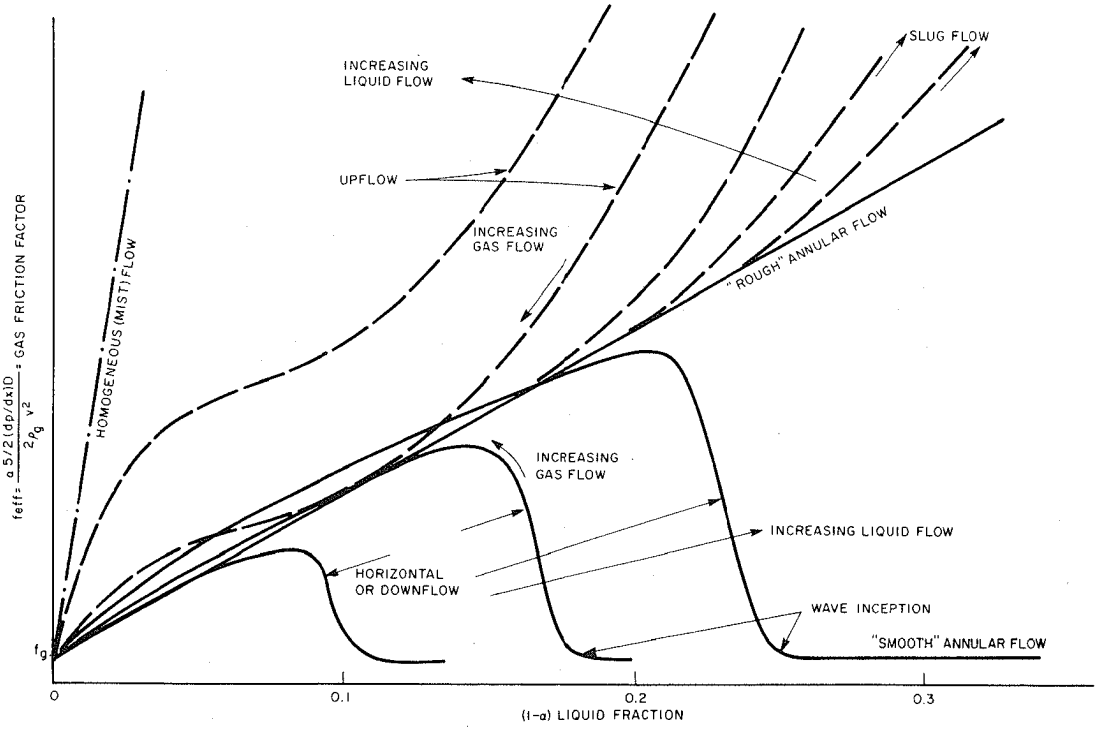

Fig. 15 Qualitative Pressure Drop Characteristics of Two-Phase Flow Regime

In adiabatic two-phase flow, the contribution of the momentum transfer to the overall pressure drop is negligibly small; theoretically, it is nonexistent if the flow is fully developed. In condensation heat transfer, the momentum transfer term contributes to the overall pressure drop due to the mass transfer that occurs at the liquid-vapor interface.

Two basic models were used in developing frictional pressure drop correlations for two-phase adiabatic flow. In the first, the flow of both phases is assumed to be homogeneous; the gas and liquid velocities are assumed equal. The frictional pressure drop is computed as if the flow were single phase, except for introducing modifiers to the single-phase friction coefficient. In the second model, the two phases are considered separate and the velocities may differ. Two correlations used to predict the frictional pressure drop are those of Lockhart-Martinelli (1949) and Dukler *et al.* (1964).

In the Lockhart-Martinelli correlation, a parameter X was defined as:

$$X = \left[\left(\frac{dp}{dz}\right)_l \div \left(\frac{dp}{dz}\right)_v\right]^{0.05} \tag{13}$$

where

$\left(\frac{dp}{dz}\right)_l$ = frictional pressure gradient, assuming that liquid alone flows in pipe

$\left(\frac{dp}{dz}\right)_v$ = frictional pressure gradient, assuming that gas (or vapor in case of condensation) alone flows in pipe

The frictional pressure gradient due to the single-phase flow of the liquid or vapor depends on the type of flow of each phase, laminar or turbulent. For turbulent flow during condensation, replace X by X_{tt}. Thus:

$$X_{tt} = \left(\frac{1-x}{x}\right)^{0.9}\left(\frac{\mu_l}{\mu_v}\right)^{0.1}\left(\frac{\rho_v}{\rho_l}\right)^{0.5} \tag{14}$$

Lockhart and Martinelli (1949) also defined ϕ_v as

$$\phi_v = \left[\left(\frac{dp}{dz}\right)_f \div \left(\frac{dp}{dz}\right)_v\right]^{0.5} \tag{15}$$

For condensation

$$\left(\frac{dp}{dz}\right)_v = -\frac{2 f_o (xG)^2}{\rho_v D_i} \tag{16}$$

where

$$f_o = 0.045 \Big/ \left(\frac{GxD_i}{\mu_v}\right)^{0.2} \tag{17}$$

Here f_o is the friction factor for adiabatic two-phase flow.

By analyzing the pressure drop data of simultaneous adiabatic flow of air and various liquids, Lockhart and Martinelli (1949) correlated the parameters ϕ_v and X and reported the results graphically. Soliman *et al.* (1968) approximated the graphical results of ϕ_v versus X_{tt} by:

$$\phi_v = 1 + 2.85\, X_{tt}^{0.523} \tag{18}$$

In the correlation of Dukler (1964), the frictional pressure gradient is given by:

$$\left(\frac{dp}{dz}\right)_f = -\frac{2 G^2 f_o \alpha(\lambda)\beta}{D_i \rho_{NS}} \tag{19}$$

where

f_o = single-phase friction coefficient evaluated at two-phase Reynolds number

$$= 0.0014 + 0.125\left(\frac{4\dot{M}_T\beta}{\pi D_i \mu_{NS}}\right)^{-0.32} \tag{20}$$

$$\alpha(\lambda) = 1 - (\ln\lambda)/[1.281 + 0.478\ln\lambda + 0.444(\ln\lambda)^2 + 0.094(\ln\lambda)^3 + 0.00843(\ln\lambda)^4] \tag{21}$$

$$\beta = \left[\left(\frac{\rho_l}{\rho_{NS}}\right)\frac{\lambda^2}{(1-\psi)} + \left(\frac{\rho_v}{\rho_{NS}}\right)\frac{(1-\lambda)^2}{\psi}\right] \tag{22}$$

$$\rho_{NS} = [\rho_l\lambda + \rho_v(1-\lambda)] \tag{23}$$

$$\mu_{NS} = [\mu_l\lambda + \mu_v(1-\lambda)] \tag{24}$$

$$\lambda = 1\Big/\left(1 + \frac{x}{(1-x)}\frac{\rho_v}{\rho_e}\right) \tag{25}$$

Since the correlations mentioned here were originally developed for adiabatic two-phase flow, Luu and Bergles (1980) modified the friction coefficients in Equations (16) and (19), using the modifier suggested by Silver and Wallis (1965). The modification replaced the friction coefficient f_o with the friction coefficient f_{co}; f_o and f_{co} are related by

$$(f_{co}/f_o) = \exp(\epsilon/2f_o) - (\xi/f_o) \tag{26}$$

where
$$\xi = (D_i\psi/2x)\left(\frac{dx}{dz}\right) \tag{27}$$

Since the Lockhart-Martinelli and Dukler correlations for the frictional pressure gradient were based on the separated flow model, so should the momentum pressure gradient. Thus:

$$\left(\frac{dp}{dz}\right)_m = -G^2\left(\frac{dx}{dz}\right)\left\{\frac{2x}{\rho_v\psi} - \frac{2(1-x)}{\rho_l(1-\psi)} + q_l\left[\frac{\psi(1-x)}{x(1-\psi)\rho_l} - \frac{x(1-\psi)}{\psi(1-x)\rho_v}\right]\right\} \tag{28}$$

To determine $(dp/dz)_m$, the void fraction ψ and the quality gradient must be known. A generalized expression for ψ was suggested by Butterworth (1975):

$$\psi = \frac{1}{1 + A_l[(1-x)/x]^{q_l}(\rho_v/\rho_l)^{r_l}(\mu_l/\mu_v)^{S_l}} \tag{29}$$

where A_l, q_l, r_l, and S_l are constants and are listed for the various correlations in Table 5.

Table 5 Constants in Equation (29) for Different Void Fraction Correlations

Model	A_l	q_l	r_l	S_l
Homogeneous (Collier 1972)	1.0	1.0	1.0	0
Lockhart-Martinelli (1949)	0.28	0.64	0.36	0.07
Baroczy (1963)	1.0	0.74	0.65	0.13
Thom (1964)	1.0	1.0	0.89	0.18
Zivi (1964)	1.0	1.0	0.67	0
Turner-Wallis (1965)	1.0	0.72	0.40	0.08

The quality gradient dx/dz in Equation (28) can be estimated by assuming a constant rate of cooling. In the case of complete condensation, its value is $-1/L$, where L is the length of the condenser tube.

Evaporators and condensers often have valves, tees, bends, and other fittings that contribute to the overall pressure drop of the heat exchanger. Collier (1972) summarizes methods predicting the two-phase pressure drop in these fittings.

ENHANCED SURFACES

Enhanced heat transfer surfaces are used in heat exchangers to improve performance and decrease cost. Condensing heat transfer is often enhanced with circular fins attached to the external surfaces of tubes to increase the area of heat transfer. Other enhancement methods, such as porous coatings, integral fins, and reentrant cavities, are used to augment boiling heat transfer on the external surfaces of evaporator tubes. Webb (1981) surveys external boiling surfaces and compares the performances of several enhanced surfaces with the performances of smooth tubes. Since the heat transfer coefficient for the refrigerant side is often smaller than the coefficient for the water side, enhancing the refrigerant-side surface can reduce the size of the heat exchanger and improve performance.

Internal fins increase the heat transfer coefficients during evaporation or condensation in tubes. However, internal fins increase the refrigerant pressure drop and reduce the heat transfer rate by decreasing the available temperature difference between hot and cold fluids. Designers should carefully determine the number of parallel refrigerant passes that give optimum loading for best overall heat transfer.

For additional information on enhancement methods in two-phase flow, consult Bergles' comprehensive surveys (1976, 1985).

SYMBOLS

A = area
A_{ef} = total effective area [Eq. (7a), Table 3]
a = local acceleration [Eq. (16), Table 1], void fraction [Eqs. (9) and (10)]
a_f = area of one side of one film
B = boiling number [Eq. (10), Table 2]
b = breadth of a condensing surface. For vertical tube, pd; for horizontal tube, $b = 2L$
c = a coefficient or constant
c_p = specific heat at constant pressure
c_v = specific heat at constant volume
c_1, c_2 = special constants (see Table 2)
c_{sf}, c_r = special constants (see Table 1)
D = diameter
D_i = inside tube diameter
D_o = outside tube diameter
d = diameter; or prefix meaning differential
(dp/dz) = pressure gradient
$(dp/dz)_f$ = frictional pressure gradient
$(dp/dz)_l$ = frictional pressure gradient, assuming that liquid alone is flowing in pipe
$(dp/dz)_m$ = momentum pressure gradient
$(dp/dz)_v$ = frictional pressure gradient, assuming that gas (or vapor) alone is flowing in pipe
F = special coefficient [Eq. (14), Table 3]
F_c = Reynolds number factor (Table 2 and Figure 10)
F_1, F_2 = condensing coefficient factors (Table 4)
f = friction factor for single-phase flow
f' = friction factor for gas flow inside pipes with wetted walls (Figure 13)
f_{co} = friction factor in presence of condensation [Eq. (26)]
f_o = friction factor [Eqs. (17) and (19)]
G = mass velocity
Gr = Grashof number
g = gravitational acceleration
g_o = gravitational constant
h = heat transfer coefficient
h_{fg} = latent heat of vaporization or of condensation
j = Colburn j factor
K = mass transfer coefficient
k = thermal conductivity
L = length
L_{mf} = mean length of fin [Eq. (7a), Table 3]
ln = natural logarithm
M = mass; or molecular weight
M_m = mean molecular weight of vapor-gas mixture
M_v = molecular weight of condensing vapor
m = general exponent [Eq. (1) or (6), Table 1]
$\dot{m}$ = mass rate of flow
N = number of tubes in vertical tier
Nu = Nusselt number
n = general exponent [Eq. (1) or (6), Table 1 and Eq. (1), Table 2]
p = pressure
p_c = critical thermodynamic pressure for coolant
Pr = Prandtl number
Q = total heat transfer
q = rate of heat transfer
r = radius
Ra = Rayleigh number
Re = Reynolds number
S = distance along flow direction
S_c = suppression factor (Table 2 and Figure 11)
T = absolute temperature
t = temperature
U = overall heat transfer coefficient
V = linear velocity
w = mass rate of flow of condensate, per unit of breadth (see Condensing)
x = quality, *i.e.*, vapor fraction = w_v/w; or distance in dt/dx
X_{tt} = parameter [Figure 10, Table 2, and Eq. (14)]
x,y,z = lengths along principal coordinate axes
Y_g = mole fraction of gas [Eqs. (2) and (3)]
Y_v = mole fraction of vapor [Eq. (3)]
α = thermal diffusivity = $k/\rho c_p$
$\alpha(\lambda)$ = ratio of two-phase friction factor to single-phase friction factor at two-phase Reynolds number [Eq. (21)]
β = ratio of two-phase density to no-slip density [Eq. (22)]
Δ = difference between values
ϵ = roughness of interface
Λ = special coefficient [Eq. (13) through (15), Table 1]
λ = ratio of liquid volumetric flow rate to total volumetric flow rate [Eq. (25)]
μ = absolute viscosity
μ_l = dynamic viscosity of saturated liquid
μ_{NS} = dynamic viscosity of two-phase homogeneous mixture [Eq. (24)]
μ_v = dynamic viscosity of saturated vapor
ν = kinematic viscosity
ρ = density
ρ_l = density of saturated liquid
ρ_{NS} = density of two-phase homogeneous mixture [Eq. (23)]
ρ_v = density of saturated vapor phase
σ = surface tension
ϕ = fin efficiency, Martinelli factor [Eq. (11)]
ϕ_v = Lockhart-Martinelli parameter [Eq. (15)]
ψ = void fraction

Subscripts and Superscripts

a = exponent in Eq. (1)
b = bubble
c = critical or cold (fluid)
cg = condensing
e = equivalent
eff = effective
f = film or fin
g = gas
h = horizontal or hot (fluid) or hydraulic
i = inlet or inside
if = interface
L = liquid
l = liquid
m = mean
mac = convective mechanism [Eq. (2), Table 2]

max = maximum
mic = nucleation mechanism [Eq. (2), Table 2]
min = minimum
o = outside or outlet or overall
r = root (fin) or reduced pressure
s = surface or secondary heat transfer surface
sat = saturation (pressure)
t = temperature or terminal temperature of tip (fin)
v = vapor or vertical
w = wall
∞ = bulk
$*$ = reference

CHAPTER 5

MASS TRANSFER

Molecular Diffusion 5.1
Convection of Mass 5.5
Simultaneous Heat and Mass Transfer between Water-Wetted Surfaces and Air .. 5.11
Symbols 5.15

MASS transfer by either molecular diffusion or convection is the transport of one component of a mixture, relative to the motion of the mixture, and is the result of a *concentration gradient.* In an air-conditioning process, water vapor is added or removed from the air, with a simultaneous transfer of heat and mass (water vapor) between the airstream and a wetted surface. The wetted surface can be water droplets in an air washer, wetted slats of a cooling tower, condensate on the surface of a dehumidifying coil, surface presented by a spray of liquid absorbent, or wetted surfaces of an evaporative condenser. The performance of equipment with these phenomena must be calculated carefully because of the simultaneous heat and mass transfer processes.

This chapter addresses the principles of mass transfer and provides methods of solving a simultaneous heat and mass transfer problem involving air and water vapor. Emphasis is on the air-conditioning processes involving mass transfer. The formulations presented can help in analyzing the performance of specific equipment. For a discussion on the performance of air washers, cooling coils, evaporative condensers, and cooling towers, see the 1992 ASHRAE *Handbook—Systems and Equipment.*

MOLECULAR DIFFUSION

Most mass transfer problems can be analyzed by considering the diffusion of a gas into a second gas, a liquid, or a solid. In this chapter, the diffusing or dilute component is designated as component B and the other component, component A. For example, when water vapor diffuses into air, the water vapor is component B and dry air is component A. Properties with subscripts A or B are local properties of that component. Properties without subscripts are local properties of the mixture.

This chapter is divided into (1) the principles of molecular diffusion, (2) a discussion on the convection of mass, and (3) simultaneous heat and mass transfer and its application to specific equipment.

The primary mechanism of mass diffusion at ordinary temperature and pressure conditions is *molecular diffusion*, a result of density gradient. In a binary gas mixture, the presence of a concentration gradient causes transport of matter by molecular diffusion, *i.e.*, because of random molecular motion, gas B diffuses through the mixture of gases A and B in a direction that reduces the concentration gradient.

Fick's Law

The basic equation for molecular diffusion is Fick's law. Expressing the concentration of component B of a binary mixture in terms of the mass fraction (ρ_B/ρ) or mole fraction (C_B/C), Fick's law is:

$$J_B = -\rho D_v \frac{d(\rho_B/\rho)}{dy} \quad (1a)$$

$$J_B^* = -CD_v \frac{d(C_B/C)}{dy} \quad (1b)$$

The minus sign indicates that the concentration gradient is negative in the direction of diffusion. The proportionality factor D_v is the *mass diffusivity* or the *diffusion coefficient.* The diffusive mass flux J_B and the diffusive molar flux J_B^* are:

$$J_B \equiv \rho_B(v_B - v) \quad (2a)$$

$$J_B^* \equiv C_B(v_B - v) \quad (2b)$$

where $(v_B - v)$ is the velocity of component B relative to the velocity of the mixture. Bird *et al.* (1960) presented an analysis of Equations (1a) and (1b).

Equations (1a) and (1b) are equivalent forms of Fick's law. The equation used depends on the problem and individual preference. This chapter emphasizes mass analysis rather than molar analysis. However, all results can be converted to the molar form using the relation $C_B \equiv \rho_B/M_B$.

Frick's Law for Dilute Mixtures

In many mass diffusion problems, component B is dilute. The density of component B is small compared with the density of the mixture, and the variation in the density of the mixture throughout the problem is about ρ_B or less. In this case, Equation (1a) can be written as

$$J_B = -D_v (d\rho_B/dy) \quad (3)$$

when $\rho_B << \rho$, $\Delta\rho < \Delta\rho_B$.

Equation (3) can be used without significant error for water vapor diffusing through air at atmospheric pressure and a temperature less than 27 °C. In this case, $\rho_B < 0.02\rho$, where ρ_B is the density of water vapor and ρ is the density of moist air (air and water vapor mixture). The error in J_B caused by replacing ρ $[d(\rho_B/\rho)/dy]$ with $d\rho_B/dy$ is less than 2%. At temperatures below 60 °C where $\rho_B < 0.10\rho$, Equation (3) can still be used if errors in J_B as great as 10% are tolerable.

Fick's Law for Mass Diffusion through Solids or Stagnant Fluids

Fick's law can be simplified for cases of dilute mass diffusion in solids, stagnant liquids, or stagnant gases. In these cases, $\rho_B << \rho$ and $v = 0$, which yields the approximate result, $J_B = \dot{m}_B''$. That is,

$$J_B = \rho_B(v_B - v) = \rho_B(v_B - \rho_B v_B/\rho) \cong \rho_B v_B = \dot{m}_B'' \quad (4)$$

Therefore, Fick's law reduces to:

$$\dot{m}_B'' = -D_v (\rho_B/dy) \quad (5)$$

when $\rho_B << \rho$, $\Delta\rho < \Delta\rho_B$, $v_A = 0$.

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Fick's Law for Ideal Gases with Negligible Temperature Gradient

For cases of dilute mass diffusion, Fick's law can be written in terms of pressure gradient instead of concentration gradient when gas B can be approximated as ideal

$$p_B = \rho_B R_U T / M_B \tag{6}$$

and when the gradient in T is small. Under these conditions, Equation (3) can be written as

$$J_B = - M_B D_v / R_U T (dp_B/dy) \tag{7a}$$

or

$$J_B^* = - D_v / R_U T (dp_B/dy) \tag{7b}$$

when B is dilute and ideal and T = is constant. Also, under the above conditions, Equation (5) may be written as

or
$$\dot{m}_B'' = - M_B D_v / R_U T (d\rho_B/dy) \tag{8a}$$

$$\dot{m}_B''^* = - D_v / R_U T (d\rho_B/dy) \tag{8b}$$

when B is dilute and ideal, $v_A = 0$, and T = constant.

The pressure gradient formulation for mass transfer analysis has been used extensively; this is unfortunate, since the pressure formulation, Equations (7) and (8), applies only to cases where one component is dilute, the fluid closely approximates an ideal gas, and the temperature gradient has a negligible effect. The density (or concentration) gradient formulation expressed in Equations (2) through (5) is the more general formulation and can be applied to a wider range of mass transfer problems, including cases where neither component is dilute [Equation (1)]. The gases need not be ideal, nor the temperature gradient negligible. Consequently, this chapter emphasizes the density formulation.

Diffusion Coefficient

For a binary mixture, the diffusion coefficient D_v is a function of temperature, pressure, and composition. Experimental measurements of D_v for most binary mixtures are limited in range and accuracy. Table 1 gives a few experimental values for diffusion of some gases in air. For more detailed tables, see the references at the end of this chapter.

Without data, use equations developed from (1) theory or (2) theory with constants adjusted from limited experimental data. For binary gas mixtures at low pressure, D_v is inversely proportional to pressure, increases with increasing temperature, and is almost independent of composition for a given gas pair. The following equation for estimating D_v at pressures less than 0.1 $p_{c\,min}$ was developed by Bird *et al.* (1960) from kinetic theory and corresponding-states arguments.

Table 1 Mass Diffusivities for Gases in Air*

Gas	D, ft²/h
Ammonia	1.08
Benzene	0.34
Carbon dioxide	0.64
Ethanol	0.46
Hydrogen	1.60
Oxygen	0.80
Water vapor	0.99

*Gases at 77°F and 14.696 psi.

$$D_v = a \left(\frac{T}{\sqrt{T_{cA} + T_{cB}}}\right)^b \left(\frac{1}{M_A} + \frac{1}{M_B}\right)^{0.5} \times \left(\frac{(p_{cA}p_{cB})^{0.33} (T_{cA}T_{cB})^{0.42}}{p}\right) \tag{9}$$

where

D_v = diffusion coefficient, ft²/h
a = constant
b = constant, dimensionless
T = absolute temperature, K
p = pressure, psi
M = molecular weight, lb_m/lb mol

The subscripts cA and cB refer to the critical state of the two gases. Analysis of experimental data gave the following values of the constants a and b:

For nonpolar gas pairs:

$$a = 7.266 \times 10^{-3}$$
$$b = 1.823$$

For water vapor with a nonpolar gas:

$$a = 9.635 \times 10^{-3}$$
$$b = 2.334$$

A *nonpolar gas* is one for which the intermolecular forces are independent of the relative orientation of molecules, depending only on the separation distance from each other. Air, composed of nonpolar gases O_2 and N_2, is nonpolar.

Equation (9) is stated to agree with experimental data at atmospheric pressure to within about 8% (Bird *et al.* 1960).

The mass diffusivity D_v for binary mixtures at low pressure is predictable within about 10% by kinetic theory (Reid *et al.* 1987).

$$D_v = 0.722 \frac{T^{1.5}}{(\sigma_{AB})^2 \Omega_{D,AB} p} \left(\frac{1}{M_A} + \frac{1}{M_B}\right)^{0.5} \tag{10}$$

where

σ_{AB} = characteristic molecular diameter, nm
$\Omega_{D,AB}$ = temperature function, dimensionless

D_v is in ft²/h, p in atmospheres, and T in kelvins. If the gas molecules of A and B are considered rigid spheres having diameters σ_A and σ_B [and $\sigma_{AB} = (\sigma_A/2) + (\sigma_B/2)$, all expressed in nanometers], the dimensionless function $\Omega_{D,AB}$ equals unity. More realistic models for the molecules having intermolecular forces of attraction and repulsion lead to values of $\Omega_{D,AB}$ that are functions of temperature. Reid *et al.* (1987) present tabulations of this quantity. These results show that D_v increases as the 2.0 power of T at low temperatures and as the 1.65 power of T at very high temperatures.

The diffusion coefficient of moist air has been calculated for Equation (9), using a simplified intermolecular potential field function for water vapor and air (Mason and Monchick 1965).

An empirical equation for mass diffusivity of water vapor in air up to 2000°F is (Sherwood and Pigford 1952):

$$D_v = (0.00215/p) [T^{2.5}/T + 441)] \tag{11}$$

where D_v is in ft²/h, p in psi, and T in °R.

Analogy between Heat and Mass Diffusion

Molecular diffusion is, in some cases, directly analogous to conduction heat transfer. Both result from random molecular

mixing in a stagnant fluid, or in a fluid in laminar (streamline) flow. The equation governing each process can be expressed in the form:

$$\text{Flux} = \text{Diffusivity} \times \text{Concentration gradient}$$

Examination of Equation (5) reveals that Fick's law applied to mass diffusion of a dilute gas through solids and stagnant fluids is analogous to Fourier's law:

$$q'' = -k\,dt/dx \tag{12}$$

The usefulness of the analogy can be proven as follows. Transient mass diffusion in a dilute mixture region where D_v is constant and component A is stagnant is governed by the following system of equations:

$$\frac{\partial \rho_B}{\partial \tau} = D_v\left(\frac{\partial^2 \rho_B}{\partial x^2} + \frac{\partial^2 \rho_B}{\partial y^2} + \frac{\partial^2 \rho_B}{\partial z^2}\right) \tag{13a}$$

$$\text{IC: } \rho_B = \rho_{Bi}(x, y, z) \text{ at } \tau = 0 \tag{13b}$$

$$\text{BC: } \rho_B = f(x, y, z, \tau); \text{ on boundary} \tag{13c}$$

Transient heat diffusion in a constant k and constant ρc_p region is governed by:

$$\frac{\partial t}{\partial \bar{\tau}} = \alpha\left(\frac{\partial^2 t}{\partial \bar{x}^2} + \frac{\partial^2 t}{\partial \bar{y}^2} + \frac{\partial^2 t}{\partial \bar{z}^2}\right) \tag{14a}$$

$$\text{IC: } t = t_i(\bar{x}, \bar{y}, \bar{z}) \text{ at } \tau = 0 \tag{14b}$$

$$\text{BC: } t = f(\bar{x}, \bar{y}, \bar{z}, \bar{\tau}); \text{ on boundary} \tag{14c}$$

These two systems of equations can be put in identical form by selecting the following dimensionless parameters:

$$\theta \equiv \frac{t - t_l}{t_h - t_l}, \qquad \bar{\theta} \equiv \frac{\rho_B - \rho_{Bl}}{\rho_{Bh} - \rho_{Bl}} \tag{15a}\ldots$$

$$X \equiv x/L,\ Y \equiv y/L,\ Z = z/L,\ \bar{X} \equiv \bar{x}/L,\ \bar{Y} \equiv \bar{y}/L,\ \bar{Z} \equiv \bar{z}/L$$

$$\text{Fo} \equiv \frac{\alpha \bar{\tau}}{L^2}, \qquad \bar{\tau} \equiv \frac{D_v \tau}{L^2} \tag{15j}\ldots$$

Using these parameters, the heat and mass diffusion equations become identical.

Heat diffusion:

$$\frac{\partial \theta}{\partial \text{Fo}} = \frac{\partial^2 \theta}{\partial \bar{x}^2} + \frac{\partial^2 \theta}{\partial \bar{y}^2} + \frac{\partial^2 \theta}{\partial \bar{z}^2} \tag{16a}$$

$$\text{IC: } \theta = \theta_i(X, Y, Z);\ \text{Fo} = 0 \tag{16b}$$

$$\text{BC: } \theta = F(X, Y, Z, \text{Fo}); \text{ on boundary} \tag{16c}$$

Mass diffusion:

$$\frac{\partial \bar{\theta}}{\partial \tau} = \frac{\partial^2 \bar{\theta}}{\partial x^2} + \frac{\partial^2 \bar{\theta}}{\partial y^2} + \frac{\partial^2 \bar{\theta}}{\partial z^2} \tag{17a}$$

$$\text{IB: } \bar{\theta} = \bar{\theta}_i(\bar{X}, \bar{Y}, \bar{Z});\ \bar{\tau} = 0 \tag{17b}$$

$$\text{BC: } \bar{\theta} = \bar{F}(\bar{X}, \bar{Y}, \bar{Z}, \text{Fo}_m); \text{ on boundary} \tag{17c}$$

Therefore, if $\theta_i = \bar{\theta}_i$ and $F = \bar{F}$, then $\theta = \bar{\theta}$. That is, if the two geometries are of the same shape and if the initial potential distributions θ_i and $\bar{\theta}_i$ are the same and the boundary conditions F and $\bar{F}$ are the same, then the solutions θ and $\bar{\theta}$ are the same. Therefore, all of the heat transfer solutions for steady-state and transient conduction are available for solving analogous steady-state and transient mass transfer problems when $\rho_B << \rho$, $\Delta\rho < \rho_B$, and $v_B = 0$. For further details on the analogy between heat and mass transfer, refer to Eckert and Drake (1972).

Diffusion of One Gas through Second Stagnant Gas

Figure 1 shows diffusion of one gas through a second stagnant gas. Water vapor diffuses from the liquid surface into surrounding stationary air. It is assumed that local equilibrium exists through the gas mixture, that the gases are ideal, and that the Gibbs-Dalton law is valid, which implies that the temperature gradient has a negligible effect. Water vapor diffuses because of concentration gradient and is given by Equation (7a). There is a continuous gas phase, so the mixture pressure p is constant, and the Gibbs-Dalton law yields:

$$p_A + p_B = p = \text{constant} \tag{18a}$$

or

$$\rho_A/M_A + \rho_B/M_B = p/R_U T = \text{constant} \tag{18b}$$

The partial pressure gradient of the water vapor causes a partial pressure gradient of the air such that:

$$dp_A/dy = -dp_B/dy$$

or

$$\frac{1}{M_A}\left(\frac{d\rho_A}{dy}\right) = -\frac{1}{M_B}\left(\frac{d\rho_B}{dy}\right) \tag{19}$$

Air, then, diffuses toward the liquid water interface. Since it cannot be absorbed there, a bulk velocity v of the gas mixture is established in a direction away from the liquid surface, so that the net transport of air is zero, *i.e.*, the air is stagnant.

$$\dot{m}_A'' = -D_v\left(\frac{d\rho_A}{dy}\right) + \rho_A v = 0 \tag{20}$$

The bulk velocity v not only transports air but also water vapor away from the interface. Therefore, total rate of water vapor diffusion is:

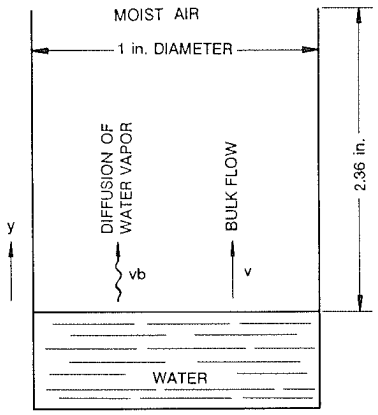

Fig. 1 Diffusion of Water Vapor through Stagnant Air

$$\dot{m}''_B = -D_v\left(\frac{d\rho_B}{dy}\right) + \rho_B v \tag{21}$$

Substituting for the velocity from Equation (20) and using Equations (18b) and (19) gives:

$$\dot{m}''_B = \frac{D_v M_B p}{\rho_A R_U T}\left(\frac{d\rho_A}{dy}\right) \tag{22}$$

Integration yields:

$$\dot{m}''_B = \frac{D_v M_B p}{R_U T}\left(\frac{\ln(\rho_{AL}/\rho_{AO})}{y_L - y_O}\right) \tag{23a}$$

or

$$\dot{m}''_B = -D_v P_{Am}\left(\frac{\rho_{BL} - \rho_{BO}}{y_L - y_O}\right) \tag{23b}$$

where

$$P_{AM} \equiv \frac{p}{p_{AL}}\rho_{AL}\left(\frac{\ln(\rho_{AL}/\rho_{AO})}{\rho_{AL} - \rho_{AO}}\right) \tag{24}$$

P_{AM} is the logarithmic mean density factor of the stagnant air. The pressure distribution for this type of diffusion is illustrated in Figure 2. *Stagnant* refers to the net behavior of the air; it does not move because the bulk flow exactly offsets diffusion. The term P_{AM} in Equation (23b) approximately equals unity for dilute mixtures, such as water vapor in air at near atmospheric conditions. This condition makes it possible to simplify Equation (23) and implies that in the case of dilute mixtures, the partial pressure distribution curves in Figure 2 are straight lines.

Example 1. A vertical tube of 1-in. diameter is partially filled with water so that the distance from the water surface to the open end of the tube is 2.362 in., as shown in Figure 1. Perfectly dried air is blown over the open tube end, and the complete system is at a constant temperature of 59°F. In 200 h of steady operation, 0.00474 lb of water evaporates from the tube. The total pressure of the system is 14.696 psia. Using these data, (a) calculate the mass diffusivity of water vapor in air and (b) compare this experimental result with that from Equation (11).

Solution:

(a) The mass diffusion flux of water vapor from the water surface is:

$$\dot{m}_B = 0.00474/200 = 0.0000237$$

The cross-sectional area of a 1-in. diameter tube is $\pi\,(1)^2/(4 \times 144) = 0.005454\ \text{ft}^2$. Therefore, $\dot{m}''_B = 1.207 \times 10^6\ \text{lb/ft}^2 \cdot \text{s}$. The partial densities are determined with the aid of the psychrometric tables.

$$\rho_{BL} = 0;\ \rho_{BO} = 0.000801\ \text{lb/ft}^3$$
$$\rho_{AL} = 0.0765\ \text{lb/ft}^3;\ \rho_{AO} = 0.0752\ \text{lb/ft}^3$$

Since $p = p_{AL} = 1$ atm, the logarithmic mean density factor [Equation (24)] is:

$$P_{AM} = 0.0765\left(\frac{\ln(0.0765/0.0752)}{(0.0765 - 0.0752)}\right) = 1.009$$

The mass diffusivity is now computed from Equation (23b) as:

$$D_v = \frac{-\dot{m}''_B(y_L - y_O)}{P_{AM}(\rho_{BL} - \rho_{BO})} = \frac{-(0.000001207)(2.362)(3600)}{(1.009)(0 - 0.000801)}$$
$$= 1.058\ \text{ft}^2/\text{h}$$

(b) By Equation (11) with $p = 14.696$ psi; $T = 59 + 460 = 519$°R

$$D_v = \frac{0.00215}{14.696}\left(\frac{519^{2.5}}{519 + 441}\right) = 0.935\ \text{ft}^2/\text{h}$$

Neglecting the correction factor P_{AM} for this example results in only a 1% change in the calculated experimental value of D_v.

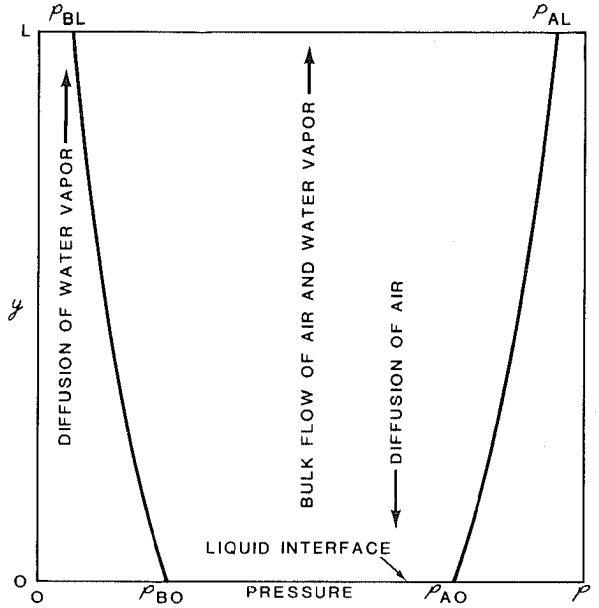

Fig. 2 Pressure Profiles for Diffusion of Water Vapor through Stagnant Air

Molecular Diffusion in Liquids and Solids

Because of the greater density, diffusion is slower in liquids than in gases. No satisfactory molecular theories have been developed for calculating diffusion coefficients. The limited measured values of D_v show that, unlike gas mixtures at low pressures, the diffusion coefficient for liquids varies appreciably with concentration.

Reasoning largely from analogy to the case of one-dimensional diffusion in gases and employing Fick's law as expressed by Equation (5):

$$\dot{m}''^*_B = D_v(C_{B1} - C_{B2})/(y_1 - y_2) \tag{25}$$

where C_B = molal concentration of solute in solvent, lb·mol/ft³.

Equation (25) expresses the steady-state diffusion of the solute B through the solvent A, in terms of the molal concentration difference of the solute at two locations separated by the distance $\Delta y = y_1 - y_2$. Bird *et al.* (1960), Hirschfelder *et al.* (1954), Sherwood and Pigford (1952), Reid and Sherwood (1966), Treybal (1952), and Eckert and Drake (1972) provide equations and tables for evaluating D_v. Hirschfelder *et al.* (1954) provide comprehensive treatment of the molecular developments.

Diffusion through a solid when the solute is dissolved to form a homogeneous solid solution is known as *structure-insensitive* diffusion (Treybal 1952). This solid diffusion closely equates diffusion through fluids, and Equation (25) can be applied to one-dimensional steady-state problems. Values of mass diffusivity are generally lower than they are for liquids and vary with temperature.

The flow of a liquid or gas through the interstices and capillaries of a porous or granular solid is a concern. The fundamental mechanism of transport differs for gaseous diffusion. It is

considered a form of molecular diffusion called *structure sensitive*. Experimental measurements are important because of the complex geometry of the flow passages. Generally, a factor $\bar{\mu}$ called permeability, is defined by the following equation:

$$\dot{m}''_B = -D_v d\rho_B/(dRT) = \bar{\mu}\,(\Delta p_B/\Delta y) \tag{26}$$

For moisture transfer through a porous building material of thickness Δy, the water vapor pressure gradient $\Delta p_B/\Delta y$ is expressed as in. Hg per inch of thickness, and the mass flux in grains/h·ft^2, so that the permeability $\bar{\mu}$ has the units of grains in/h·ft^2·in. Hg. Chapter 21 has further information.

CONVECTION OF MASS

Convection of mass involves the mass transfer mechanisms of molecular diffusion and bulk fluid motion. Fluid motion in the region adjacent to a mass transfer surface is laminar or turbulent, depending on geometry and flow conditions.

Mass Transfer Coefficient

Convective mass transfer is analogous to convective heat transfer where geometry and boundary conditions are similar. The analogy holds for both laminar and turbulent flows and applies to both external and internal flow problems.

Mass Transfer Coefficients for External Flows

Most convective mass transfer problems can be solved with an appropriate relationship that relates the mass transfer flux (to or from an interfacial surface) to the concentration difference across the boundary layer illustrated in Figure 3. This formulation gives rise to the convective mass transfer coefficient defined by:

$$h_m \equiv \dot{m}''_B/(\rho_{Bi} - \rho_{B\infty}) \tag{27}$$

where

h_m = local external mass transfer coefficient, ft/h
$\dot{m}''_B$ = mass flux of gas B from surface, lb$_m$/ft^2·h
ρ_{Bi} = concentration or density of gas B at interface, lb$_m$/ft^3
$\rho_{B\infty}$ = density of component B outside boundary layer

If ρ_{Bi} and $\rho_{B\infty}$ are constant over the entire interfacial surface, the mass transfer rate from the surface can be expressed as:

$$\dot{m}''_B = \bar{h}_m(\rho_{Bi} - \rho_{B\infty}) \tag{28}$$

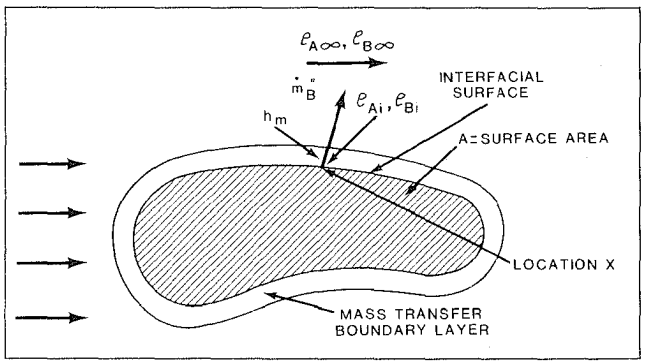

Fig. 3 Nomenclature for Convective Mass Transfer from External Surface at Location X where Surface is Impermeable to Gas A

where $\bar{h}_m$ is the average mass transfer coefficient defined as:

$$\bar{h}_m \equiv \frac{1}{A}\int_A h_m\, dA \tag{29a}$$

Mass Transfer Coefficients for Internal Flows

Most internal convective mass transfer problems, such as those that occur in channels or in the cores of dehumidification coils, can be solved if an appropriate relationship is available to relate the mass transfer flux (to or from the interfacial surface) to the difference between the concentration at the surface and the bulk concentration in the channel, as illustrated in Figure 4. This formulation leads to the definition of the mass transfer coefficient for internal flows:

$$h_m \equiv \dot{m}''_B/(\rho_{Bi} - \rho_{Bb}) \tag{29b}$$

where

h_m = internal mass transfer coefficient, ft/h
$\dot{m}''_B$ = mass flux of gas B at interfacial surface, lb$_m$/ft^2·h
ρ_{Bi} = density of gas B at interfacial surface, lb$_m$/ft^3
$\rho_{Bb} \equiv 1/(\bar{u}_B A_{cs}\int_{A_{cs}} u_B \rho_B dA_{cs})$ = bulk density of gas B at location x
$\bar{u}_B \equiv 1/(A_{cs}\int_A u_B\, dA_{cs})$ = average velocity of gas B at location x, ft/min
A_{cs} = cross-sectional area of channel at station x, ft^2
u_B = velocity of component B in x direction, ft/min
ρ_B = density distribution of component B at station x, lb$_m$/ft^3

Often, it is easier to obtain the bulk density of gas B from:

$$\rho_{Bb} = (\dot{m}_{BO} + \int_A \dot{m}''_B\, dA)/(\bar{u}_B\, A_{cs}) \tag{30}$$

where

$\dot{m}_{BO}$ = mass flow rate of component B at station x = 0, lb$_m$/h
A = interfacial area of channel between station x = 0 and station x = x, ft^2

Equation (30) can be derived from the preceding definitions. The major problem is the determination of $\bar{u}_B$. If, however, the analysis is restricted to cases where B is dilute and concentration gradients of B in the x direction are negligibly small, $\bar{u}_B \cong \bar{u}$. Component B is swept along in the x direction with an average velocity equal to the average velocity of the dilute mixture.

Analogy between Convective Heat and Mass Transfer

Most expressions for the convective mass transfer coefficient h_m are determined from expressions for the convective heat transfer coefficient h.

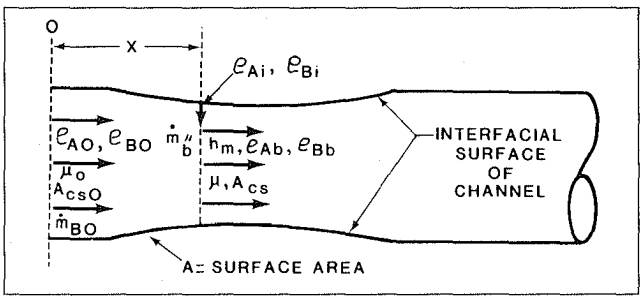

Fig. 4 Nomenclature for Convective Mass Transfer from Internal Surface Impermeable to Gas A

For problems in internal and external flow where mass transfer occurs at the convective surface and where component B is dilute, it was shown by Bird *et al.* (1960) and Incropera and DeWitt (1990) that:

$$\text{Nu} = f(X, Y, Z, \text{Pr}, \text{Re}) \text{ and } \overline{\text{Nu}} = g(\text{Pr}, \text{Re}) \qquad (31), (32)$$

and

$$\text{Sh} = f(X, Y, Z, \text{Sc}, \text{Re}) \text{ and } \overline{\text{Sh}} = g(\text{Sc}, \text{Re}) \qquad (33), (34)$$

where the function f is the same in Equations (31) and (33), and the function g is the same in Equations (32) and (34). The quantities Pr and Sc are dimensionless Prandlt and Schmidt numbers, respectively, as defined in the Symbols section. The primary restrictions on the analogy are that the surface shapes are the same and that the dimensionless temperature boundary conditions are analogous to the dimensionless density distribution boundary conditions for component B, as indicated in Equations (16) and (17). Several primary factors prevent the analogy from being perfect. In some cases, the Nusselt number was derived for smooth surfaces. Many mass transfer problems involve wavy, droplet-like, or roughened surfaces. Many Nusselt number relations are obtained for constant temperature surfaces. Sometimes ρ_{Bi} is not constant over the entire surface because of varying saturation conditions and the possibility of surface dryout.

In all mass transfer problems, there is some blowing or suction at the surface because of the condensation, evaporation, or transpiration of component B. In most cases, this blowing/suction phenomenon has little effect on the Sherwood number, but the analogy should be examined closely if $v_i/u_\infty > 0.01$ or $v_i/\bar{u} > 0.01$, especially if the Reynolds number is large.

Example 2. Use the analogy expressed in Equations (32) and (34) to solve the following problem. An expression for heat transfer from a constant-temperature flat plate in laminar flow is:

$$\overline{\text{Nu}}_L = 0.644\ \text{Pr}^{1/3}\ \text{Re}_L^{1/2} \qquad (35)$$

Using the heat/mass transfer analogy, determine the mass transfer rate and temperature of the water-wetted flat plate in Figure 5.

Solution: To solve the problem, properties should be evaluated at film conditions. However, since the plate temperature and the interfacial water vapor density are not known, a first estimate will be obtained assuming the plate T_{i1} to be at 77 °F. The plate Reynolds number is:

$$\text{Re}_{L1} = \frac{\rho u_\infty L}{\mu} = \frac{(0.0728\ \text{lb/ft}^3)\ (1970\ \text{ft/min})\ (0.328\ \text{ft})}{(1.32 \times 10^{-5}\ \text{lb·ft/s})\ (60\ \text{s/min})} = 59{,}340$$

The plate is entirely in laminar flow, since the transitional Reynolds number is about 5×10^5. Using the mass transfer analogy, Equation (35) yields:

$$\overline{\text{Sh}}_{L1} = 0.664\ \text{Sc}^{1/3}\ \text{Re}_L^{1/2}$$
$$= 0.664\ (0.35)^{1/3}\ (59{,}340)^{1/2} = 114$$

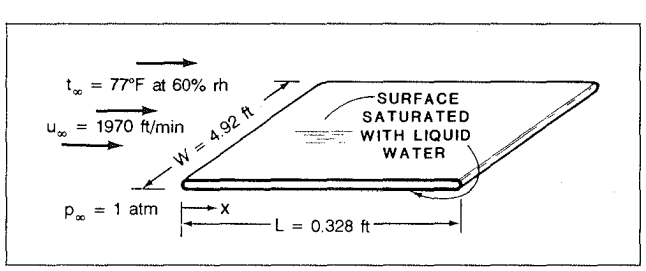

Fig. 5 Water Saturated Flat Plate in Flowing Airstream

From the definition of the Sherwood number:

$$\bar{h}_{m1} = \overline{\text{SL}}_L\ D/L = (114)\ (3.87 \times 10^{-4}\ \text{ft}^2\text{/s})/0.328\ \text{ft} = 0.135\ \text{ft/s}$$

The psychrometric tables give a humidity ratio of 0.0121 at 77 °F and 60% rh. Therefore,

$$\rho_{B\infty} = (0.0121)\ \rho_{A\infty} = (0.0121)(0.0728\ \text{lb/ft}^3) = 0.000881\ \text{lb/ft}^3$$

Psychrometric tables give the saturation density for water at 77 °F as

$$\rho_{Bi1} = (0.02016)\ \rho_{A\infty} = (0.02016)\ (0.0728\ \text{lb/ft}^3) = 0.001468\ \text{lb/ft}^3$$

Therefore, the mass transfer rate from the double-sided plate is

$$\dot{m}_{B1} = \bar{h}_m A(\rho_{Bi} - \rho_{B\infty})$$
$$= (0.135\ \text{ft/s})\ (0.328\ \text{ft} \times 4.92\ \text{ft})\ (2)\ (0.001468 - 0.000881)\ \text{lb/ft}^3$$
$$= 0.000255\ \text{lb/s}$$

This mass rate, transformed from the liquid state to the vapor state, requires the following heat rate to the plate to maintain the evaporation:

$$q_{i1} = \dot{m}''_B h_{fg} = (0.000255\ \text{lb/s})\ (1050\ \text{Btu/lb}) = 0.268\ \text{Btu/s}$$

To obtain a second estimate of the wetted plate temperature in this type of problem, the following criteria are used. Calculate the T_i necessary to provide a heat rate of q_{i1}. If this temperature T_{iq1} is above the dew-point temperature T_{id}, set the second estimate at $T_{i2} = (T_{iq1} + T_{i1})/2$. If T_{iq1} is below the dew-point temperature, set $T_{i2} = (T_{id} + T_{i1})/2$. For this problem, the dew point is $T_{id} = 57$ °F.

Obtaining the second estimate of the plate temperature requires an approximate value of the heat transfer coefficient.

$$\overline{\text{Nu}}_{L1} = 0.664\ \text{Pr}^{1/3}\ \text{Re}_L^{1/2} = 0.664\ (0.708)^{1/3}\ (59{,}340)^{1/2}$$
$$= 144.2$$

From the definition of the Nusselt number:

$$\bar{h}_1 = \overline{\text{Nu}}_L\ k/L = (144.2)\ (0.0151\ \text{Btu/h·ft·°F})\ (0.328\ \text{ft})$$
$$= 6.63\ \text{Btu/h·ft}^2\text{·°F}$$

Therefore, the second estimate for the plate temperature is

$$T_{iq1} = T_\infty - q_i/(\bar{h}A)$$
$$= 77\,°\text{F} - (0.268\ \text{Btu/s})\ (3600\ \text{s/h})\ (663\ \text{Btu/h·ft}^2\text{·°F})\ (3.228\ \text{ft}^2)$$
$$= 77\,°\text{F} - 45\,°\text{F} = 32\,°\text{F}$$

This temperature is below the dew-point temperature; therefore,

$$T_{i2} = (57\,°\text{F} + 77\,°\text{F})/2 = 67\,°\text{F}$$

The second estimate of the film temperature is

$$T_{f2} = (T_{i2} + T_\infty)/2 = (67\,°\text{F} + 77\,°\text{F})/2 = 72\,°\text{F}$$

The next iteration on the solution is as follows:

$$\text{Re}_{L2} = 61{,}010$$
$$\overline{\text{Sh}}_{L2} = 0.664\ (0.393)^{1/3}\ (61{,}010)^{1/2} = 120$$
$$\bar{h}_{m2} = (120)\ (3.63 \times 10^{-4})/(0.328) = 0.133\ \text{ft/s}$$

The free stream density of the water vapor has been evaluated. The density of the water vapor at the plate surface is the saturation density at 67 °F.

$$\rho_{Bi2} = (0.01374)(0.0739\ \text{lb/ft}^3) = 0.00101\ \text{lb/ft}^3$$
$$A = 2 \times 4.92 \times 0.328 = 3.228\ \text{ft}^2$$
$$\dot{m}_{B2} = (0.133\ \text{ft/s})(3.228\ \text{ft}^2)(0.00101\ \text{lb/ft}^3 - 0.000881\ \text{lb/ft}^3)$$
$$= 0.0000554\ \text{lb/s}$$
$$\dot{q}_{i2} = (0.0000554)(1056) = 0.0585\ \text{Btu/s}$$
$$\overline{\text{Nu}}_{L2} = 0.644\,(0.709)^{1/3}\,(61{,}000)^{1/2} = 146$$
$$\bar{h}_2 = (146)(0.01493)/(0.328) = 6.65\ \text{Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F}$$
$$T_{iq2} = 77{}^\circ\text{F} - (0.0585)(3600)/(6.65)(3.228) = 67.2{}^\circ\text{F}$$

This temperature is above the dew-point temperature; therefore

$$T_{i3} = (T_{iq2} + T_{i2})/2 = (67 + 67.2)/2 = 67.1{}^\circ\text{F}$$

This is approximately the same result as that obtained in the previous iteration. Therefore, the problem solution is:

$$T_i = 67{}^\circ\text{F}$$
$$\dot{m}_B = 0.199\ \text{lb/h}$$

Eddy Diffusivity

Turbulent flow is characterized by random velocity fluctuations superimposed on the time-average velocity. The fluctuations occur in the direction of flow and normal to it. Small mixing actions or *eddy currents* are established within the turbulent flow field. The eddies cause an exchange of momentum between different layers of the moving fluid. If the fluid has a temperature gradient, energy is exchanged by this mixing action in much the same way. If a mass concentration gradient exists, a similar mass exchange known as *eddy diffusion* occurs, which is relatively faster than molecular diffusion and depends on the *intensity* of the velocity fluctuations, or turbulence. Since intensity of turbulence is determined by the Reynolds number of the flow, the rate of eddy diffusion depends on the Reynolds number (Sherwood and Pigford 1952). The *eddy diffusivity* ϵ_D is defined by the same form of equation as that in molecular diffusion [Equation (5)]:

$$\dot{m}''_B = \epsilon_D\,(d\rho_B/dy)$$

where ϵ_D = eddy diffusivity, ft²/h.

Because data on eddy diffusivities are difficult to obtain, the mass transfer coefficient, analogous to the heat transfer coefficient in convective heat transfer, is usually defined and determined experimentally.

Application to Turbulent Flow

Consider an airstream in steady turbulent flow over a wetted surface (Figure 6). The liquid-vapor interface is assumed to be at zero velocity, which results in a slow-moving layer of fluid in laminar flow next to the surface. Between this *laminar sublayer* and the main body of the turbulent stream, a transition region or buffer layer exists, in which the fluid may be alternately in laminar flow and in turbulent flow. Within the laminar sublayer, only molecular diffusion can occur; in the buffer layer, both molecular and eddy diffusion contribute to mass transfer. In the turbulent region, eddy diffusion predominates and is so rapid that it almost equalizes the concentration gradient.

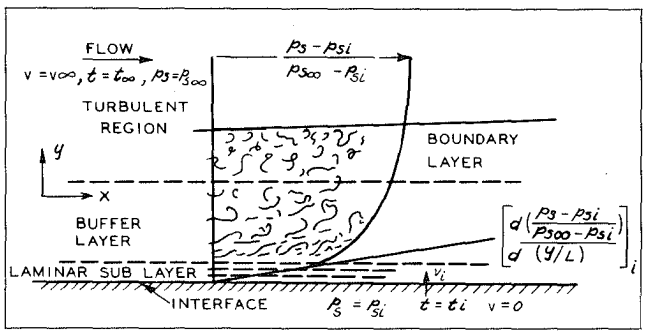

Fig. 6 Turbulent Diffusion Boundary Layer on Flat Surface

Because of the presence of the laminar sublayer, the rate of molecular mass diffusion from the wetted surface to the airstream, from Equation (6), is:

$$J_B = -D_v\,(d\rho_B/dy)_i$$

where $(d\rho_B/dy)_i$ is the partial pressure gradient at the interface. Assuming that the gases are ideal and obey the Gibbs-Dalton law, and that the total pressure is constant, then a partial pressure gradient must also exist in the air. The wetted surface is impermeable to air, so a convective or bulk velocity must be established to counter the air diffusion rate. The total mass transfer from the wetted surface to the airstream must then be given by:

$$\dot{m}''_B = -D_v\,(d\rho_B/dy)_i + \rho_{Bi}\,v_i \qquad (37)$$

where v_i is the convective velocity of the component B vapor at the interface (Figure 6), and the partial mass density of the water vapor at the interface is:

$$\rho_{Bi} = M_B p_{Bi}/R_U T_i$$

For the diffusion of one gas through a second stagnant gas, the simple molecular diffusion equation corrected by the factor P_{AM} [Equation (24)] accounts for the mass transfer contribution of the convective velocity. For dilute mixtures, as in Example 1, this contribution is small. The same correction factor can be used for this forced convection mass transfer process—at least at low mass transfer rates where v_i is small. The total mass transfer rate from the interface is:

$$\dot{m}''_B = -D_v P_{AM}\,(d\rho_B/dy)_i \qquad (38)$$

The concentration gradient $(d\rho_B/dy)_i$ must be evaluated experimentally. Rather than work with this gradient, a mass transfer coefficient h_m may be defined as in Equation (27). It follows that:

$$\dot{m}''_B = (h_m M_B/R_U)(p_{Bi} - p_{B\infty})$$
$$= -(M_B D_v P_{AM}/R_U T_i)(dp_B/dy)_i$$

By mathematical rearrangement, this becomes:

$$\text{Sh}_L = h_m L/D$$
$$= P_{AM}\left[d\left(\frac{p_B - p_{Bi}}{p_{B\infty} - p_{Bi}}\right) / d\,(y/L)\right]_i \qquad (39)$$

where Sh_L is the dimensionless Sherwood number and L is some characteristic dimension of the mass transfer surface, such as the length of a plate or diameter of a cylinder. Equation (39) gives a simple, physical interpretation of the dimensionless mass transfer coefficient, *i.e.*, the Sherwood number. It is a measure of the dimensionless concentration gradient at the interface or mass transfer boundary (Figure 6).

Bird *et al.* (1960), Hirschfelder *et al.* (1954), Sherwood and Pigford (1952), Incropera and DeWitt (1990), and Reid *et al.* (1987) experimentally established mass transfer coefficients for a number of flow geometries. Because of the analogy between these

transfer processes, heat transfer data have been used to predict mass transfer coefficients. The reliability of such similar relations has been well-established at low mass transfer rates for some flow geometries.

Analogy Relations for Convective Mass Transfer

Heat transfer from the wetted surface of Figure 6 to the airstream can be expressed in an analogous form to that of mass transfer. Therefore, the heat flux per unit area is:

$$\dot{q}'' = -k\,(dt/dy)_i = h\,(t_i - t_\infty)$$

or, by mathematical rearrangement:

$$\mathrm{Nu} = hL/k = d\left(\frac{t - t_i}{t_\infty - t_i}\right) / d(y/L) \qquad (40)$$

The dimensionless Nusselt number Nu of heat transfer is the dimensionless temperature gradient at the heat transfer boundary (interface), and the Sherwood and Nusselt numbers are analogous expressions for dimensionless mass transfer and heat transfer coefficients, respectively.

For momentum transfer, a friction factor f is defined so that the momentum flux at the interface τ_i per unit area is:

$$\tau_i = \mu(du/dy)_i = f\rho\bar{u}^2/2$$

or

$$f/2(\rho\bar{u}L/\mu) = \left[\frac{d(u/\bar{u})}{d(y/L)}\right]_i \qquad (41)$$

where $\bar{u}$ = mean free stream velocity of gas, ft/h.

Equation (41) states that one-half the friction factor times the Reynolds number ($\mathrm{Re} = \rho\bar{u}L/\mu$) equals the dimensionless velocity gradient at the stationary surface or interface.

Equations (39), (40), and (41) show the similarity of mass, heat, and momentum transport in a turbulent boundary layer (with both eddy and molecular diffusion), and Equations (11), (6), and (7) demonstrate the similarity for a laminar boundary layer (with only molecular diffusion). Again, assume a gaseous system in which, by chance, $D_v = \alpha = \nu$ (*i.e.*, the molecular diffusion constants for mass, energy, and momentum are identical). Theoretically, the eddy diffusivities for these three rate processes are identical, since experiments verify they rely on the same particle mixing action for the transfer operation. Therefore, the dimensionless partial pressure, temperature, and velocity profiles must be identical. This permits equating the left side of Equations (39), (40), and (41) to obtain

$$\mathrm{Sh}_L = \mathrm{Nu}_L = (f/2)\,(\mathrm{Re}_L)$$

or

$$h_m L/DP_{AM} = hL/k = (f/2)\,(\bar{u}L/\nu) \qquad (42)$$

This is equivalent to the statement that the Prandtl number ($\mathrm{Pr} = c_p\mu/k$) and Schmidt number ($\mathrm{Sc} = \mu/\rho D_v$) are unity. Using this statement, Equation (42) can be rearranged to give:

$$\frac{\mathrm{Sh}}{\mathrm{Re\,Sc}} = \frac{\mathrm{Nu}}{\mathrm{Re\,Pr}} = \frac{f}{2} \qquad (43a)$$

or

$$h_m/\bar{u}P_{AM} = h/\rho c_p\bar{u} = f/2 \qquad (43b)$$

The two right-hand terms of Equation (43) are known as the *Reynolds analogy*. The left-hand term is an extension of the Reynolds analogy to include mass transfer. The Reynolds analogy gives a plausible correlation between friction factors and heat transfer coefficients for common gases (where $\mathrm{Pr} \cong 1$) with moderate temperature potential. Since Reynolds developed this analogy, at least five modified analogies have been suggested to account for the effect of the Prandtl number. One of the simplest and most often used is the one suggested by Chilton and Colburn (1934), who showed that the correlation of heat transfer data with friction data could be improved by substituting $(\mathrm{Pr})^{1/3}$ for Pr in Equation (43a), which leads to:

$$j_H = \left(\frac{h}{\rho c_p\bar{u}}\right)\left(\frac{c_p\mu}{K}\right)^{2/3} = \mathrm{St\,Pr}^{2/3} = f/2 \qquad (44)$$

By analogy, Chilton and Colburn suggested mass transfer data could be represented with good accuracy by a similar change in the Schmidt number parameter:

$$j_D = \left(\frac{h_m P_{AM}}{\bar{u}}\right)\left(\frac{\mu}{\rho D_v}\right)^{2/3} = \mathrm{St}_m\mathrm{Sc}^{2/3} = f/2 \qquad (45)$$

where St and St_m refer to the dimensionless Stanton numbers for heat and mass transfer, respectively (see Symbols section for definition of St).

Equations (44) and (45) are known as the *j-factor analogy* and are widely used for plotting and predicting heat and mass transfer data.

The power of the Chilton-Colburn j-factor analogy is represented in Figures 7 through 10. Figure 7 plots various experimental values of j_D from a flat plate with flow parallel to the plate surface. The solid line, which represents the data to near perfection, is actually $f/2$ from Blasius' solution of laminar flow on a flat plate (left-hand portion of the solid line) and Goldstein's solution for a turbulent boundary layer (right-hand portion). The right-hand portion of the solid line also represents McAdams' (1954) correlation of turbulent flow heat transfer coefficient for a flat plate.

A *wetted-wall column* is a vertical tube in which a thin liquid film adheres to the tube surface and exchanges mass by evaporation or absorption with a gas flowing through the tube. Figure 8

illustrates typical data on vaporization in wetted-wall columns, plotted as j_D versus Re. The spread of the points with variation in $\mu/\rho D_v$ results from Gilliland's finding of an exponent of 0.56, not 2/3, representing the effect of the Schmidt number. Gilliland's equation can be written as follows:

$$j_D = 0.023\ \mathrm{Re}^{-0.17}\ (\mu/\rho D_v)^{0.11} \tag{46}$$

Similarly, McAdams' (1954) equation for heat transfer in pipes can be expressed as:

$$j_H = 0.023\ \mathrm{Re}^{-0.20}\ (c_p\mu/k)^{0.07} \tag{47}$$

This is represented by the dashed curve in Figure 8, which falls below the mass transfer data. The curve $f/2$ representing friction in smooth tubes is the upper solid curve.

Data for the evaporation of liquids from single cylinders into gas streams flowing transversely to the cylinders' axes are shown in Figure 9. Although the dash-dot line on Figure 9 represents the data, it is actually taken from McAdams (1954) as representative of a large collection of data on heat transfer to single cylinders placed transverse to airstreams. To compare these data with friction, it is necessary to distinguish between total drag and skin friction. Since the analogies are based on skin friction, the normal pressure drag must be subtracted from the measured total drag. At Re = 1000, the skin friction is 12.6% of the total drag; at Re = 31,600, it is only 1.9%. Consequently, the values of $f/2$ at a high Reynolds number, obtained by the difference, are subject to considerable error.

In Figure 10, data on the evaporation of water into air for single spheres are presented. The solid line, which best represents these data, agrees with the dashed line representing McAdams' correlation for heat transfer to spheres. These results cannot be compared with friction or momentum transfer, since total drag has not been allocated to skin friction and normal pressure drag. Application of these data to air-water contacting devices such as air washers and spray cooling towers is well substantiated.

When the temperature of the heat exchanger surface in contact with moist air is below the dew-point temperature of the air, vapor condensation occurs. Typically, the air dry-bulb temperature and humidity ratio both decrease as the air flows through the exchanger. Therefore, sensible and latent heat transfer occur simultaneously. This process is similar to one that occurs in a spray dehumidifier and can be analyzed using the same procedure; however, this is not generally done.

Cooling coil analysis and design is complicated by the problem of determining transport coefficients h, h_m, and f. It would be convenient if heat transfer and friction data for dry heating coils could be used with the Colburn analogy to obtain the mass transfer coefficients. However, this approach is not always reliable, and work by Guillory and McQuiston (1973) and Helmer (1974) shows that the analogy is not consistently true. Figure 11 shows j factors for a simple parallel plate exchanger for different surface conditions with sensible heat transfer. Mass transfer j factors and the friction factors exhibit the same behavior. Dry surface j factors fall below those obtained under dehumidifying conditions with the surface wet. At low Reynolds numbers, the boundary layer grows quickly; the droplets are soon covered and have little effect on the flow field. As the Reynolds number is increased, the boundary layer becomes thin and more of the total flow field is exposed to the droplets. The roughness caused by the droplets induces mixing and larger j factors. The data in Figure 11 cannot be applied to all surfaces, because the length of the flow channel is also an important variable. However, the water collecting on the surface is mainly responsible for breakdown of the j factor analogy. The j factor analogy is approximately true when the surface

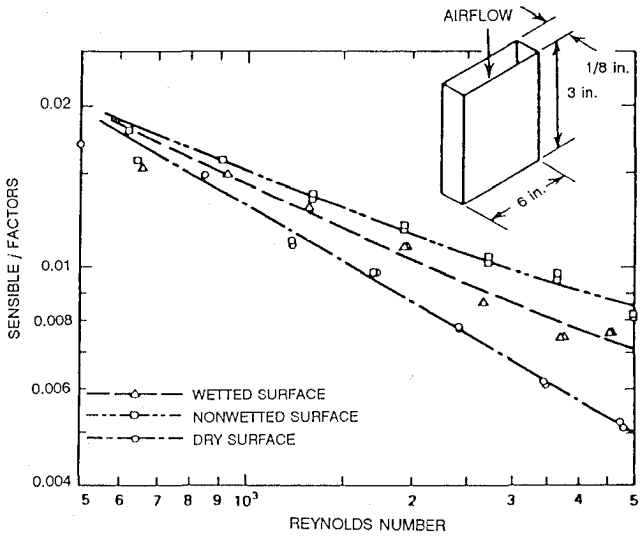

Fig. 11 Sensible Heat Transfer j-Factors for Parallel Plate Exchanger

conditions are identical. Under some conditions, it is possible to obtain a film of condensate on the surface instead of droplets. Guillory and McQuiston (1973) and Helmer (1974) related dry sensible j and f factors to those for wetted dehumidifying surfaces.

The equality of j_H, j_D, and $f/2$ for certain streamline shapes at low mass transfer rates has experimental verification. For flow past bluff objects, j_H and j_D are much smaller than $f/2$, based on total pressure drag. The heat and mass transfer, however, still relate in a useful way by equating j_H and j_D.

Example 3. Using solid cylinders of volatile solids (*e.g.*, naphthalene, camphor, dichlorobenzene) with airflow normal to these cylinders, Bedingfield and Drew (1950) found that the ratio between the heat and mass transfer coefficients could be closely correlated by the relation:

$$h/\rho h_m = [(0.294 \text{ Btu/lb}_m \cdot °\text{F})\,(\mu/\rho D_v)]^{0.56}$$

For completely dry air at 70°F flowing at a velocity of 31 fps over a wet-bulb thermometer of diameter $d = 0.300$ in., determine the heat and mass transfer coefficients from Figure 9 and compare their ratio with the Bedingfield-Drew relation.

Solution: For dry air at 70°F, $\rho = 0.075$ lb/ft^3, $\mu = 0.0441$ lb/ft·h, $k = 0.0150$ Btu/h·ft·°F, and $c_p = 0.2398$ Btu/lb$_m$·°F. From Equation (11), $D_v = 0.971$ ft^2/h. Therefore:

$$\text{Re}_{da} = \rho u_\infty d/\mu = 0.075 \times 31 \times 3600 \times 0.300/(12 \times 0.0441) = 4740$$
$$\text{Pr} = c_p\mu/k = 0.2398 \times 0.0441/0.0150 = 0.706$$
$$\text{Sc} = \mu/\rho D_v = 0.0441/(0.075 \times 0.971) = 0.605$$

From Figure 9 at $\text{Re}_{da} = 4740$, $j_H = 0.0088$, $j_D = 0.0099$, and

$$h = j_H \rho c_p U_\infty/(\text{Pr})^{2/3}$$
$$h = 0.0088 \times 0.075 \times 0.2398 \times 31 \times 3600/(0.706)^{2/3}$$
$$= 22.3 \text{ Btu/h·ft}^2\text{·°F}$$
$$h_m = j_D U_\infty(\text{Sc})^{2/3} = 0.0099 \times 31/(0.605)^{2/3}$$
$$= 0.429 \text{ ft/s}$$
$$h/\rho h_m = 22.3/(0.075 \times 0.429 \times 3600) = 0.193 \text{ Btu/lb}_m\text{·°F}$$

From the Bedingfield and Drew relation:

$$h/\rho h_m = 0.294\,(0.605)^{0.56} = 0.222 \text{ Btu/lb}_m\text{·°F}$$

The Reynolds analogy, Equation (43b), suggests that $h/\rho h_m = c_p = 0.2398$ Btu/lb$_m$·°F. This close agreement is because the ratio Sc/Pr is 0.605/0.706 or 0.86, so that the exponent of these numbers has little effect on the ratio of the transfer coefficients.

The extensive developments for calculating heat transfer coefficients can be applied to calculate mass transfer coefficients under similar geometrical and flow conditions using the j-factor analogy. For example, Chapter 3 lists equations for calculating heat transfer coefficients for flow inside and normal to pipes. Each equation can be used for mass transfer coefficient calculations by equating j_H and j_D, and imposing the same restriction to each stated in Chapter 3. Similarly, mass transfer experiments often replace corresponding heat transfer experiments with complex geometries where exact boundary conditions are difficult to model (Sparrow and Ohadi 1987a, 1987b).

The j-factor analogy is useful only at low mass transfer rates. As the rate of mass transfer increases, the movement of matter normal to the transfer surface increases the convective velocity [v_i in Equation (37) and Figure 6]. For example, if a gas is blown from many small holes in a flat plate placed parallel to an airstream, the boundary layer thickens, and resistance to both mass and heat transfer increases with the increasing blowing rate. Heat transfer data are usually collected at zero or, at least, insignificant mass transfer rates. Therefore, if such data are to be valid for a mass transfer process, the mass transfer rate, *i.e.*, the blowing, must be low.

The j-factor relationship, $j_H = j_D$, can still be valid at high mass transfer rates, but neither j_H nor j_D can be represented by data at zero mass transfer conditions. Chapter 18 of Eckert and Drake (1972) and Chapter 24 of Bird *et al.* (1960) have detailed information on high mass transfer rates.

Lewis Relation

Heat and mass transfer coefficients are satisfactorily related, at the same Reynolds number, by equating the Chilton-Colburn j-factors. This leads to:

$$h_m/\bar{u}\,P_{AM}\,(\mu/\rho D_v)^{2/3} = (h/\rho c_p\,\bar{u})(c_p\mu/k)^{2/3}$$

or

$$h/h_m\rho c_p = (P_{AM})[\mu/\rho D_v/(c_p\mu/k)]^{2/3}$$
$$= (P_{AM})(\alpha/D_v) \qquad (48)$$

The quantity α/D_v is the Lewis number Le. Its magnitude expresses relative rates of propagation of energy and mass within a system. It is fairly insensitive to temperature variation. For air and water vapor mixtures, the ratio is (0.60/0.71) or 0.845, and $(0.845)^{2/3}$ is 0.894. At low diffusion rates, where the heat-mass transfer analogy is valid, P_{AM} is essentially unity. Therefore, for air and water vapor mixtures:

$$h/h_m\rho c_p = 1 \qquad (49)$$

The ratio of the heat transfer coefficient to the mass transfer coefficient is equal to the specific heat per unit volume at constant pressure of the mixture. This relation is usually called the Lewis relation and is nearly true for air and water vapor at low mass transfer rates. It is generally not true for other gas mixtures because the ratio of thermal to vapor diffusivity Le can differ from unity. The agreement between wet-bulb temperature and adiabatic saturation temperature is a direct result of the nearness of Lewis number to unity for air and water vapor.

The Lewis relation is valid in turbulent flow whether or not the ratio of α/D_v equals 1, because eddy diffusion in turbulent flow involves the same mixing action for heat exchange as for mass exchange, and this action overwhelms any molecular diffusion. Deviations from the Lewis relation are, therefore, due to a laminar boundary layer or a laminar sublayer and buffer zone, as in

Figure 6, where molecular transport phenomena are the controlling factors.

SIMULTANEOUS HEAT AND MASS TRANSFER BETWEEN WATER-WETTED SURFACES AND AIR

A simplified method used to solve simultaneous heat and mass transfer problems was developed using the Lewis relation and gives satisfactory results for most air-conditioning processes. Extrapolation to very high mass transfer rates, where the simple heat-mass transfer analogy is not valid, will lead to erroneous results.

Enthalpy Potential

The water vapor concentration in the air is the humidity ratio W defined as:

$$W \equiv \rho_B/\rho_A \tag{50}$$

A mass transfer coefficient is defined using W as the driving potential:

$$\dot{m}_B'' = K_m(W_i - W_\infty) \tag{51}$$

where the coefficient K_m has the units $lb_m/h \cdot ft^2$. For dilute mixtures $\rho_{Ai} \cong \rho_{A\infty}$ (*i.e.*, the partial mass density of dry air changes by only a small percentage between interface and free stream conditions). Therefore:

$$\dot{m}_B'' = (K_m/\rho_{Am})(\rho_{Bi} - \rho_\infty) \tag{52}$$

where ρ_{Am} is the *mean* density of dry air, lb_m/ft^3. Comparing this equation with Equation (27) shows that:

$$h_m = K_m/\rho_{Am} \tag{53}$$

The *humid* specific heat c_{pm} of the airstream is, by definition (Mason and Monchick 1965),

$$c_{pm} = (1 + W_\infty)C_p \quad \text{Btu} \cdot \text{lb(dry air)} \cdot °\text{F}$$

or

$$c_{pm} = (\rho/\rho_{A\infty})c_p \tag{54}$$

Substituting from these expressions into the Lewis relation [Equation (49)] gives:

$$(h\rho_{Am}/K_m\rho_{A\infty}c_{pm}) = 1 \cong (h/K_m c_{pm}) \tag{55}$$

since $\rho_{Am} \cong \rho_{A\infty}$, because of the small change in dry-air density. Using a mass transfer coefficient with humidity ratio as the driving force, the Lewis relation becomes: ratio of heat to mass transfer coefficient equals humid specific heat.

For the plate humidifier illustrated in Figure 5, the total heat transfer from liquid to interface is:

$$\dot{q}'' = \dot{q}_A'' + \dot{m}_B'' h_{fg}$$

Using the definitions of the transfer coefficients:

$$\dot{q}'' = h(t_i - t_\infty) + K_m(W_i - W_\infty)h_{fg}$$

Assuming Equation (55) is valid:

$$\dot{q}'' = K_m[c_{pm}(t_i - t_\infty) + (W_i - W_\infty)h_{fg}] \tag{56}$$

The enthalpy of the air is approximately:

$$h = c_{pa}t + Wh_s \tag{57}$$

The enthalpy of the water vapor h_s by the ideal gas law can be expressed as:

$$h_s = c_{ps}(t - t_o) + h_{fgo}$$

where the base of enthalpy is taken as saturated water at temperature t_o. Choosing $t_o = 0°F$ to correspond with the base of the dry-air enthalpy gives:

$$h = (c_{pa} + Wc_{ps})t + Wh_{fgo} = c_{pm}t + Wh_{fgo} \tag{58}$$

If small changes in the latent heat of vaporization of water with temperature are neglected when comparing Equations (57) and (58), the total heat transfer can be written as:

$$\dot{q}'' = K_m(h_i - h_\infty) \tag{59}$$

Where the driving potential for heat transfer is temperature difference and the driving potential for mass transfer is mass concentration or partial pressure, the driving potential for simultaneous transfer of heat and mass in an air water-vapor mixture is, to a close approximation, enthalpy.

Basic Equations for Direct Contact Equipment

Air-conditioning equipment can be classified by (1) whether there is direct contact between air and water used as a cooling or heating fluid, or (2) whether the heating or cooling fluid is separated from the airstream by a solid wall. Examples of the former are air washers and cooling towers; an example of the latter is a direct expansion refrigerant (or water) cooling and dehumidifying coil. In both cases, the airstream is in contact with a water surface. *Direct contact* implies a direct contact with the cooling (or heating) fluid. In the dehumidifying coil, the contact is directly with the condensate removed from the airstream, but indirectly with the refrigerant flowing inside the tubes of the coil. These two cases are treated separately because the surface areas of direct contact equipment cannot be evaluated.

For the direct contact spray chamber air washer of cross-sectional area A_{cs} and length l (Figure 12), the steady mass flow rate of dry air per unit of cross-sectional areas is:

$$\dot{m}_a/A_{cs} = G_a \tag{60}$$

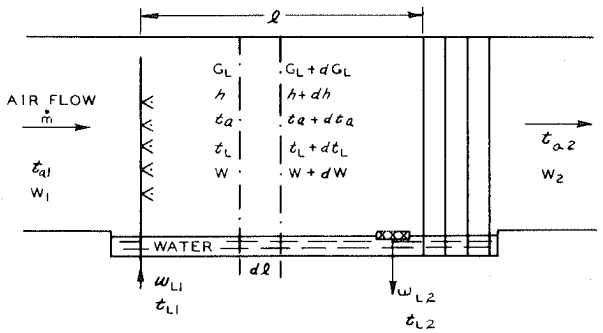

Fig. 12 Air Washer Spray Chamber

and the corresponding mass velocity of water flowing parallel with the air is:

$$\dot{m}_L/A_{cs} = G_L \tag{61}$$

where

$\dot{m}_a$ = mass flux, mass flow rate of air, lb/h
G_a = mass flux, mass velocity, or flow rate per unit cross-sectional area for air, lb/h · ft^2
$\dot{m}_L$ = mass flow rate of liquid, lb/h
G_L = mass velocity, or flow rate per unit cross-sectional area, for liquid, lb/h · ft^2

Since water is evaporating or condensing, G_L changes by an amount dG_L in a differential length dl of the chamber. Similar changes occur in temperature, humidity ratio, enthalpy, and other properties.

Since evaluating the true surface area in direct contact equipment is difficult, it is common to work on a unit volume basis. If a_H and a_M are the area of heat transfer and mass transfer surface per unit of chamber volume, respectively, the total surface areas for heat and mass transfer are:

$$A_H = a_H A_{cs} l \text{ and } A_M = a_M A_{cs} l \tag{62}$$

The basic equations for the process occurring in the differential length dl can be written for:

1. *Mass transfer*

$$-dG_L = G_a dW = K_m a_M (W_i - W) dl \tag{63}$$

That is, the water evaporated, the moisture increase of the air, and the mass transfer rate are all equal.

2. *Heat transfer to air*

$$G_a c_{pm} dt_a = h_a a_H (t_i - t_a) dl \tag{64}$$

3. *Total energy transfer to air*

$$G_a(c_{pm} dt_a + h_{fgo} dW) = [K_m a_M (W_i - W) h_{fg} + h_a a_H (t_i - t_a)] dl \tag{65}$$

As shown in the preceding section, assuming $a_H = a_M$, Le = 1, and neglecting small variations in h_{fg}, Equation (65) reduces to:

$$G_a dh = K_m a_M (h_i - h) dl \tag{66}$$

The heat and mass transfer areas of spray chambers are assumed to be identical ($a_H = a_M$). Where packing materials, such as wood slats or Raschig rings, are used, the two areas may be considerably different because the packing may not be wet uniformly. The validity of the Lewis relation was discussed previously. It is not necessary to account for the small changes in latent heat h_{fg} after making the two previous assumptions.

4. *Energy balance*

$$G_a dh = \pm G_L c_L dt_L \tag{67}$$

A minus sign refers to parallel flow of air and water; a plus sign refers to counterflow (water flow in the opposite direction from airflow).

The water flow rate changes between inlet and outlet as a result of the mass transfer. For exact energy balance, the term $(c_L t_L dG_L)$ should be added to the right side of Equation (67). The percentage change in G_L is quite small in usual applications of air-conditioning equipment and, therefore, can be ignored.

5. *Heat transfer to water*

$$G_L c_L dt_L = h_L a_H (t_L - t_i) dl \tag{68}$$

Equations (63) to (68) are the basic relations for solution of simultaneous heat and mass transfer processes in direct contact air-conditioning equipment.

To facilitate the use of these relations in equipment design or performance, three other equations can be extracted from the above set. Combining Equations (66), (67), and (68) gives:

$$(h - h_i)/(t_L - t_i) = -(h_L a_H / K_m a_M) = -(h_L/K_m) \tag{69}$$

Equation (69) relates the enthalpy potential for the total heat transfer through the gas film to the temperature potential for this same transfer through the liquid film. Physical reasoning leads to the conclusion that this ratio is proportional to the ratio of gas film resistance ($1/K_m$) to the liquid film resistance ($1/h_L$). Combining Equations (64), (66), and the Lewis relation [Equation (55)] gives:

$$dh/dt_a = (h - h_i)/(t_a - t_i) \tag{70}$$

Similarly, combining Equations (63), (64), and the Lewis relation gives:

$$dW/dt_a = (W - W_i)/(t_a - t_i) \tag{71}$$

Equation (71) indicates that at any cross section in the spray chamber, the instantaneous slope of the air path dW/dt_a on a psychrometric chart is determined by a straight line connecting the air state with the interface saturation state at that cross section. In Figure 13, state 1 represents the state of the air entering the parallel flow air washer chamber of Figure 12. The washer is operating as a heating and humidifying apparatus so that the interface saturation state of the water at air inlet is the state designated 1_i. Therefore, the initial slope of the air path is along a line directed from state 1 to state 1_i. As the air is heated, the water cools and the interface temperature drops. Corresponding air states and interface saturation states are indicated by the letters a, b, c, and d in

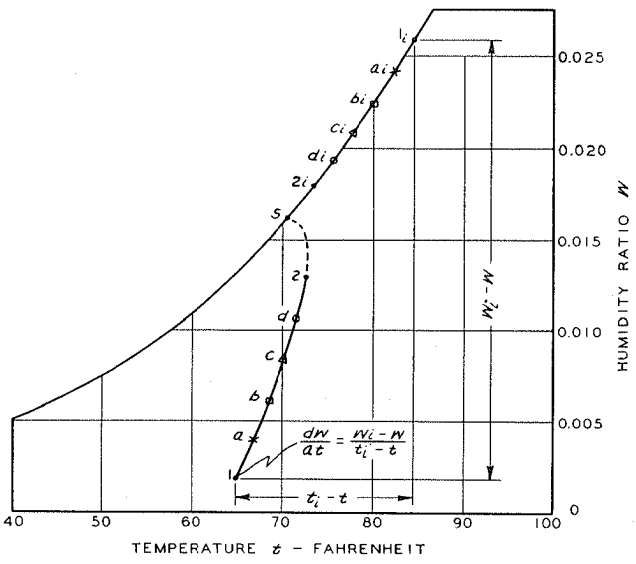

Fig. 13 Air Washer Humidification Process on Psychrometric Chart

Figure 13. In each instance, the air path is directed toward the associated interface state. The interface states are derived from Equations (67) and (69). Equation (67) describes how the air enthalpy changes with water temperature; Equation (69) describes how the interface saturation state changes to accommodate this change in air and water conditions. The solution for the interface state on the normal psychrometric chart of Figure 13 can be determined either by trial and error from Equations (67) and (69) or by a complex graphical procedure (Kusuda 1957).

Air Washers

Air washers are direct contact apparatus used to simultaneously change the temperature and humidity content of air passing through the chamber and to remove air contaminants such as dust and odors. Adiabatic spray washers, which have no external heating or chilling source, are used to cool and humidify air. Chilled spray air washers have an external chiller to cool and dehumidify air. Heated spray air washers, whose external heating source provides additional energy for evaporation of water, are used to humidify and possibly heat air.

Example 4. A parallel flow air washer with the following design conditions is to be designed (see Figure 12).

Water temperature at inlet $t_{L1} = 95\,^{\circ}F$
Water temperature at outlet $t_{L2} = 75\,^{\circ}F$
Air temperature at inlet $t_{a1} = 65\,^{\circ}F$
Air wet-bulb at inlet $t_{a1}' = 45\,^{\circ}F$
Air mass flow rate per unit area $G_a = 1200$ lb/h·ft^2
Spray ratio $G_L/G_a = 0.70$
Air heat transfer coefficient per cubic foot of chamber volume $h_a a_H = 72$ Btu/h·°F·ft^3
Liquid heat transfer coefficient per cubic foot of chamber volume $h_L a_H = 900$ Btu/h·°F·ft^3
Air volume flow rate $Q = 6500$ ft^3/min

Solution: The air mass flow rate $w_a = (6500/13.25) = 490$ lb/min, and the required spray chamber cross-sectional area is, then, $A_{cs} = w_a/G_a = 490\,(60)/1200 = 24.5$ ft^2. The mass transfer coefficient is given by the Lewis relation as:

$$K_m a_M = (h_a a_H)/c_{pm} = 72/0.24 = 300 \text{ lb/h·ft}^3$$

Figure 14 shows the enthalpy-temperature psychrometric chart with the graphical solution for the interface states and the air path through the washer spray chamber. The solution proceeds as follows:

1. Enter bottom of chart with t_{ai}' of 45 °F, follow up to saturation curve to establish air enthalpy h_1 of 17.65 Btu/lb. Extend this enthalpy line to intersect initial air temperature t_{ai}' of 65 °F (state 1 of air), and initial water temperature t_{L1} of 95 °F at point A. (Note that the temperature scale is used for both air and water temperatures.)
2. Through point A, construct the *energy balance* AB with a slope of:

$$(dh/dt_L) = -G_L/G_a = -0.7$$

Point B is determined by intersection with the leaving water temperature $t_{L2} = 75\,^{\circ}F$. The negative slope here is a consequence of the parallel flow, which results in the air-water mixture approaching, but not reaching, the common saturation state *s*. (The line AB has no physical significance in representing any *air state* on the psychrometric chart. It is merely a construction line in the graphical solution.)
3. Through point A, construct the *tie-line* A1_i having a slope of:

$$(h - h_i)(t_L - t_i) = -(h_L a_H/K_m a_M) = -(900/300) = -3$$

The intersection of this line with the saturation curve gives the initial interface state 1_i at the chamber inlet. (Note how the energy balance line and tie-line, representing Equations (67) and (69), combine for a simple graphical solution on the $h - t$ chart for the interface state.)
4. The initial slope of the air path can now be constructed, according to Equation (70), drawing line 1a toward the initial interface state 1_i. (The length of the line 1a will depend on the degree of accuracy required in the solution and the rate at which the slope of the air path is changing.)
5. Construct the horizontal line a-M locating the point M on the energy-balance line. Draw a new tie-line (slope of −3 as before) from M to a_i locating interface state a_i. Continue the air path from a to b by directing it toward the new interface state a_i. (Note that the change in slope of the air path from 1a to ab is quite small, justifying the path incremental lengths used.)
6. Continue in the manner of step 5 until point 2, when the final state of the air leaving the chamber is reached. In this example, six steps are used in the graphical construction with the following results:

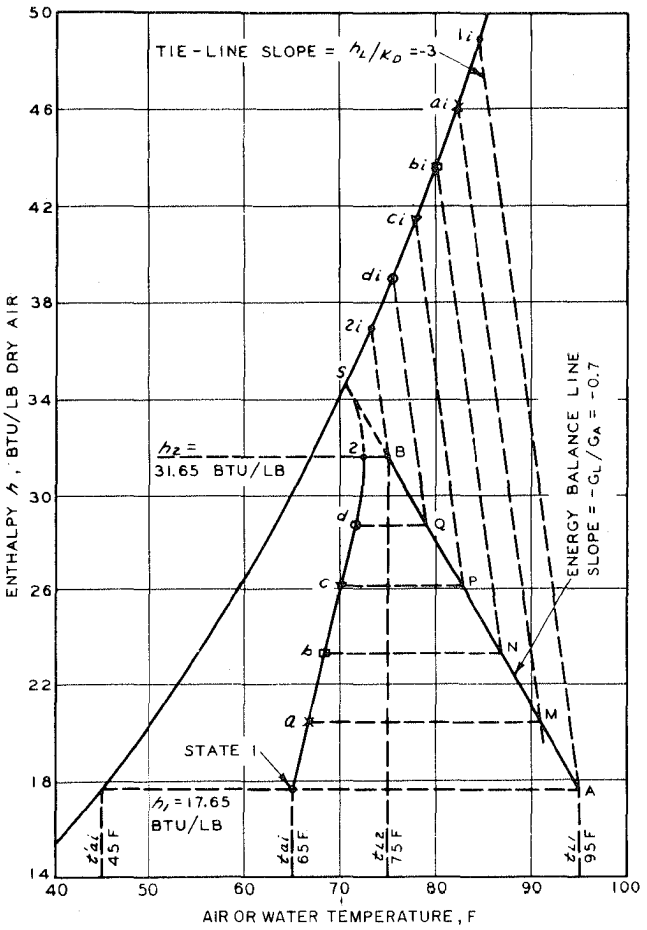

Fig. 14 Graphical Solution for Air-State Path in Parallel Flow Air Washer

State	1	a	b	c	d	2
t_L	95.0	91.0	87.0	83.0	79.0	75.0
h	17.65	20.45	23.25	26.05	28.85	31.65
t_i	84.5	82.3	80.1	77.8	75.6	73.2
h_i	49.00	46.25	43.80	41.50	39.10	37.00
t_a	65.0	66.8	68.5	70.0	71.4	72.4

The final state of the air leaving the washer is $t_{a2} = 72.4\,^{\circ}F$ and $h_2 = 31.65$ Btu/lb (wet-bulb temperature $t_{a2}' = 67\,^{\circ}F$).

7. The final step involves calculating the required length of the spray chamber. From Equation (66):

$$l = \frac{G_a}{K_m a_M} \int_1^2 \frac{dh}{(h_i - h)}$$

The integral is evaluated graphically by plotting $1/(h_i - h)$ versus h as shown in Figure 15. Any satisfactory graphical method can be used to evaluate the area under the curve. Simpson's rule with four equal increments of Δh equal to 3.5 gives:

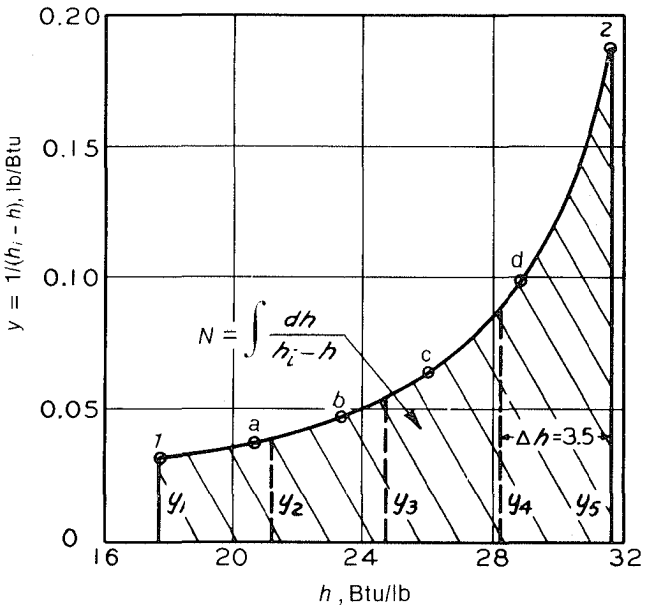

Fig. 15 Graphical Solution of $\int dh/(h_i - h)$

$$N = \int_1^2 \frac{dh}{(h_i - h)} \approx (\Delta h/3)(y_1 + 4y_2 + 2y_3 + 4y_4 + y_5)$$

$$N = (3.5/3)[(1 \times 0.0319) + (4 \times 0.0400) + (2 \times 0.0553) + (4 \times 0.0865) + (1 \times 0.1870)] = 0.975$$

The design length is, therefore, $l = (1200/300)(0.975) = 3.9$ ft.

The method used in Example 4 can also be used to predict the performance of existing direct contact equipment and can determine the transfer coefficients when performance data from test runs are available. By knowing the water and air temperatures entering and leaving the chamber and the spray ratio, it is possible, by trial and error, to determine the proper slope of the tie-line necessary to achieve the measured final air state. The tie-line slope gives the ratio $h_L a_H / K_m a_M$; $K_m a_M$ is found from the integral relationship in Example 4 from the known chamber length l.

Additional descriptions of air spray washers and general performance criteria are given in Chapter 19 of the 1992 ASHRAE *Handbook—Systems and Equipment.*

Cooling Towers

A cooling tower is a direct contact heat exchanger in which waste heat picked up by the cooling water from a refrigerator, air conditioner, or industrial process is transferred to atmospheric air by cooling the water. Cooling is achieved by breaking up the water flow to provide a large water surface for air, moving by natural or forced convection through the tower, to contact the water. Cooling towers may be counterflow, crossflow, or a combination of both.

The temperature of the water leaving the tower and the packing depth needed to achieve the desired leaving water temperature are of primary interest for design. Therefore, the mass and energy balance equations are based on an overall coefficient K, which is based on (1) the enthalpy driving force due to h at the bulk water temperature and (2) the neglecting of the film resistance. Combining Equations (66) and (67) and using the parameters described above, yields

$$G_L C_L dt = K_M a_M (h_i - h) dl = G_a dh = K_a dV (h' - h_a)/A_{cs} \quad (72)$$

or

$$K_a V/\dot{m}_L = \int_{t_1}^{t_2} C_L dt/(h' - h_a) \quad (73)$$

Chapter 37 of the 1992 ASHRAE *Handbook—Systems and Equipment* covers cooling tower design in detail.

Cooling and Dehumidifying Coils

When water vapor is condensed out of an airstream onto an extended surface (finned) cooling coil, the simultaneous heat and mass transfer problem can be solved by the same procedure set forth for direct contact equipment. The basic equations are the same, except that the true surface area of the coil A is known and the problem does not have to be solved on a unit volume basis. Therefore, if in Equations (63), (64), and (66) $a_M dl$ or $a_H dl$ is replaced by A_{cs}/dA, these equations become the basic heat, mass, and total energy transfer equations for indirect contact equipment such as dehumidifying coils. The energy balance shown by Equation (67) remains unchanged. The heat transfer from the interface to the refrigerant now encounters the combined resistances of the condensate film ($R_L = 1/h_L$), the metal wall and fins (if any) R_m, and the refrigerant film ($R_r = A/h_r A_r$). If this combined resistance is designated as $R_i = R_L + R_m + R_r = 1/U_i$, Equation (68) becomes, for a coil dehumidifier:

$$\dot{m}_L c_L dt_L = U_i (t_L - t_i) dA \quad (74)$$

(plus sign for counterflows, minus sign for parallel flow).

The tie-line slope is then:

$$(h - h_i)/(t_L - t_i) = -(U_i/K_m) \quad (75)$$

Figure 16 illustrates the graphical solution on a temperature-enthalpy (psychrometric) chart for the air path through a dehumidifying coil with a constant refrigerant temperature. Since the tie-line slope is infinite in this case, the energy balance line is

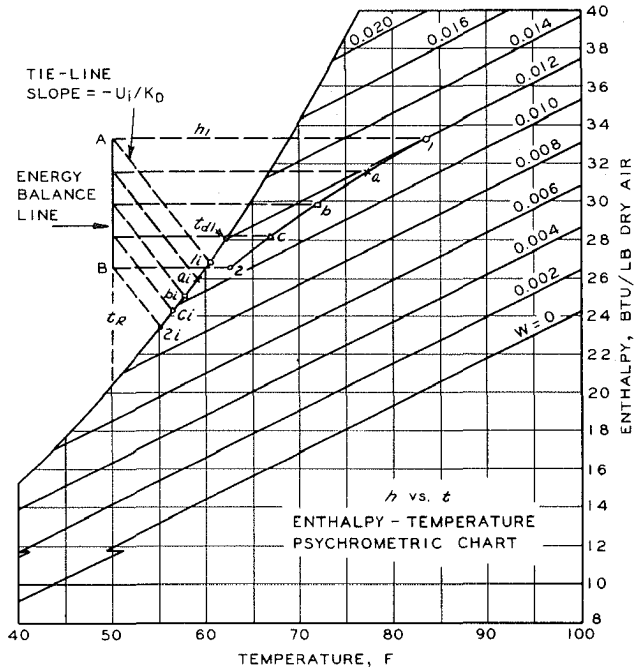

Fig. 16 Graphical Solution for Air-State Path in Dehumidifying Coil with Constant Refrigerant Temperature

vertical. The corresponding interface states and air states are denoted by the same letter symbol, and the solution follows the same procedure as in Example 4.

If the problem is to determine the required coil surface area for a given performance, the area is computed by the relation:

$$A = (\dot{m}_a/K_m)\int_1^2 dh/(h_i - h) \qquad (76)$$

This graphical solution on the psychrometric chart automatically determines whether any part of the coil is dry. Thus, in the example illustrated in Figure 16, the entering air at state 1 initially encounters an interface saturation state 1_i, clearly below its dew-point temperature t_{d1}, so the coil immediately becomes wet. Had the graphical technique resulted in an initial interface state above the dew-point temperature of the entering air, the coil would then be initially dry. The air would then follow a constant humidity ratio line (the sloping W = constant lines on the chart) until the interface state reached the air dew-point temperature.

Mizushina *et al.* (1959) developed this method not only for water vapor and air, but also for other vapor-gas mixtures. Chapter 21 of the 1992 ASHRAE *Handbook—Systems and Equipment*, based on ARI *Standard* 410, shows another related method of determining air cooling and dehumidifying coil performance.

SYMBOLS

a = constant, dimensionless; or surface area per unit volume, ft^2/ft^3
A = surface area, ft^2
A_{cs} = cross-sectional area, ft^2
b = exponent, dimensionless
C = molal concentration of solute in solvent, lb mol/ft^2
c_L = specific heat of liquid, Btu/lb·°F
c_p = specific heat at constant pressure, Btu/lb·°F
c_{pm} = specific heat of moist air at constant pressure, Btu/lb (da)·°F (Note: da = dry air)
d = diameter, ft
D_v = diffusion coefficient (mass diffusivity), ft^2/h
f = Fanning friction factor, dimensionless
Fo = Fourier number = $\alpha\tau/L^2$, dimensionless
Fo_m = mass transfer Fourier number $D_v\tau/L^2$
G = mass flux, flow rate per unit of cross-sectional area, $lb_m/h \cdot ft^2$
h = enthalpy, Btu/lb; or heat transfer coefficient, Btu/h·ft^2·°F
h_{fg} = enthalpy of vaporization, Btu/lb_m
h_m = mass transfer coefficient, ft/h
J = diffusive mass flux, $lb_m/h \cdot ft^2$
J^* = diffusive molar flux, lb mol/h·ft^2
j_D = Colburn mass transfer group = $Sh/(Re \cdot Pr^{1/3})$, dimensionless
j_H = Colburn heat transfer group = $Nu/(Re \cdot Pr^{1/3})$, dimensionless
k = thermal conductivity, Btu/h·ft^2·°F
K_m = mass transfer coefficient, lb/h·ft^2
K_{mo} = overall transfer coefficient, lb/h·ft^2
l = length, ft
L = characteristic length, ft
L/G = liquid-to-air mass flow ratio
Le = Lewis number = a/D_v, dimensionless
$\dot{m}$ = rate of mass transfer, lb/h
$\dot{m}''$ = mass flux, lb/h·ft^2
$\dot{m}''^*$ = molar flux, lb mol/h·ft^2
M = molecular weight, lb/lb mol
N = number of transfer units, dimensionless
N_o = number of overall transfer units, dimensionless
Nu = Nusselt number = hD/k, dimensionless
p = pressure, atmospheres or lb_f/ft^2
P_{AM} = logarithmic mean density factor, Eq. (24)
Pr = Prandtl number = $c_p\mu/k$, dimensionless
q = rate of heat transfer, Btu/h
q'' = heat flux per unit area, Btu/h·ft^2
Re = Reynolds number = $\rho VD/\mu$, dimensionless
R_U = universal gas constant = 1545 lb_f·ft/lb mol·R
R_i = combined thermal resistance, ft^2·°F·h/Btu
R_L = thermal resistance of condensate film, ft^2·°F·h/Btu
R_m = thermal resistance across metal wall and fins, ft^2·°F·h/Btu
R_r = thermal resistance of refrigerant film, ft^2·°F·h/Btu
Sc = Schmidt number = $\mu/\rho D_v$, dimensionless
Sh = Sherwood number = $h_D L/D_v$, dimensionless
t = temperature, °F
T = absolute temperature, °R
u = velocity in x direction, ft/min
U_i = overall conductance from refrigerant to air-water interface for dehumidifying coil, Btu/h·ft^2·°F
v = velocity in y direction, ft/min
v_i = velocity normal to mass transfer surface for component i, ft/h
V = fluid stream velocity, ft/min
W = humidity ratio, lb of water vapor per lb of dry air, lb(w)/lb(da)
x,y,z = coordinate direction, ft
X,Y,Z = coordinate direction, dimensionless
α = thermal diffusivity = $k/\rho c_p$, ft^2/h
ϵ_D = eddy mass diffusivity, ft^2/h
μ = absolute viscosity, $lb_m/ft \cdot h$
$\bar{\mu}$ = permeability, grains/h·ft^2·in. Hg/in.
ν = kinematic viscosity, ft^2/h
σ = characteristic molecular diameter, angstroms
ρ = mass density or concentration, lb_m/ft^3
$\bar{\rho}$ = molal density or concentration, lb mol/ft^3
τ = time
ω = mass fraction, lb/lb
$\Omega_{D,AB}$ = temperature function in Eq. (10)

Subscripts

a = air property
da = dry air property or air-side transfer quantity
Am = logarithmic mean
A = gas component of binary mixture
B = the more dilute gas component of binary mixture
c = critical state
H = heat transfer quantity
i = air-water interface value
L = liquid
m = mean value
M = mass transfer quantity
o = property evaluated at 0°F
s = water vapor property or transport quantity
t = total
w = water vapor
∞ = property of main fluid stream

Superscripts

j^* = on molar basis
$\bar{u}$ = average value

Transport Properties of Moist Air 6.19
Air, Water, and Steam Properties 6.20
Symbols 6.20

PSYCHROMETRICS deals with thermodynamic properties of moist air and uses these properties to analyze conditions and processes involving moist air. Hyland and Wexler (1983a, 1983b) developed formulas for thermodynamic properties of moist air and water. Perfect gas relations can be used in most air-conditioning problems instead of these formulas. Threlkeld (1970) showed that errors are less than 0.7% in calculating humidity ratio, enthalpy, and specific volume of saturated air at standard atmospheric pressure for a temperature range of −60 to 120°F. Furthermore, these errors decrease with decreasing pressure.

This chapter discusses perfect gas relations and describes their use in common air-conditioning problems. The formulas developed by Hyland and Wexler (1983a) may be used where greater precision is required.

COMPOSITION OF DRY AND MOIST AIR

Atmospheric air contains many gaseous components as well as water vapor and miscellaneous contaminants (*e.g.*, smoke, pollen, and gaseous pollutants not normally present in free air far from pollution sources).

Dry air exists when all water vapor and contaminants have been removed from atmospheric air. The composition of dry air is relatively constant, but small variations in the amounts of individual components occur with time, geographic location, and altitude. Harrison (1965) lists the approximate percentage composition of dry air by volume as: nitrogen, 78.084; oxygen, 20.9476; argon, 0.934; carbon dioxide, 0.0314; neon, 0.001818; helium, 0.000524; methane, 0.00015; sulfur dioxide, 0 to 0.0001; hydrogen, 0.00005; and minor components such as krypton, xenon, and ozone, 0.0002. The apparent molecular mass or weighted average molecular weight of all components, for *dry air* is 28.9645, based on the carbon-12 scale (Harrison 1965). The gas constant for dry air, based on the carbon-12 scale, is:

$$R_a = 1545.32/28.9645 = 53.352 \text{ ft} \cdot \text{lb}_f/\text{lb}_m \cdot {}^\circ\text{R} \quad (1)$$

Moist air is a binary (or two-component) mixture of dry air and water vapor. The amount of water vapor in moist air varies from zero (dry air) to a maximum that depends on temperature and pressure. The latter condition refers to *saturation*, a state of neutral equilibrium between moist air and the condensed water phase (liquid or solid). Unless otherwise stated, saturation refers to a flat interface surface between the moist air and the condensed phase. The molecular weight of water is 18.01528 on the carbon-12 scale. The gas constant for water vapor is:

$$R_w = 1545.32/18.01528 = 85.778 \text{ ft} \cdot \text{lb}_f/\text{lb}_m \cdot {}^\circ\text{R} \quad (2)$$

UNITED STATES STANDARD ATMOSPHERE

The temperature and barometric pressure of atmospheric air vary considerably with altitude as well as with local geographic and weather conditions. The standard atmosphere gives a standard of reference for estimating properties at various altitudes. At sea level, standard temperature is 59°F; standard barometric pressure is 29.921 in. Hg. The temperature is assumed to decrease linearly with increasing altitude throughout the troposphere (lower atmosphere), and to be constant in the lower reaches of the stratosphere. The lower atmosphere is assumed to consist of dry air that behaves as a perfect gas. Gravity is also assumed constant at the standard value, 32.1740 ft/s^2. Table 1 summarizes property data for altitudes to 60,000 ft.

THERMODYNAMIC PROPERTIES OF MOIST AIR

Table 2, developed from formulas by Hyland and Wexler (1983a, 1983b), shows values of thermodynamic properties based on the *thermodynamic temperature scale*. This ideal scale differs slightly from practical temperature scales used for physical measurements. For example, the standard boiling point for water (at 14.696 psia or 29.921 in. Hg) occurs at 211.95 °F on this scale rather than at the traditional value of 212 °F. Most measurements are currently based on the International Practical Temperature Scale of 1968 (IPTS-68) (Preston-Thomas 1976). The following paragraphs briefly describe each column of Table 2.

t = Fahrenheit temperature, based on thermodynamic temperature scale and expressed relative to absolute temperature T in degrees Rankine (°R) by the relation:

$$T = t + 459.67$$

W_s = humidity ratio *at saturation*, condition at which gaseous phase (moist air) exists in equilibrium with condensed phase (liquid or solid) at given temperature and pressure (standard atmospheric pressure). At given values of temperature and pressure, humidity ratio W can have any value from zero to W_s.

v_a = specific volume of dry air, ft³/lb.

v_{as} = $v_s - v_a$, difference between volume of moist air *at saturation*, per pound of dry air, and specific volume of dry air itself, ft³/lb of dry air, at same pressure and temperature.

v_s = volume of moist air *at saturation* per pound of dry air, ft³/lb of dry air.

h_a = specific enthalpy of dry air, Btu/lb of dry air. Specific enthalpy of dry air has been assigned a value of zero at 0 °F and standard atmospheric pressure in Table 2.

h_{as} = $h_s - h_a$, difference between enthalpy of moist air *at saturation*, per pound of dry air, and specific enthalpy of dry air itself, Btu/lb of dry air, at same pressure and temperature.

h_s = enthalpy of moist air *at saturation* per pound of dry air, Btu/lb of dry air.

h_w = specific enthalpy of condensed water (liquid or solid) in equilibrium with saturated air at specified temperature and pressure, Btu per pound of water. Specific enthalpy of liquid water is assigned a value of zero at its triple point (32.018 °F) and saturation pressure.

Note that h_w is greater than the steam-table enthalpy of saturated pure condensed phase by the amount of enthalpy increase governed by the pressure increase from saturation pressure to 1 atmosphere plus influences from presence of air.

s_a = specific entropy of dry air, Btu/lb·°R. In Table 2, specific entropy of dry air has been assigned a value of zero at 0 °F and standard atmospheric pressure.

s_{as} = $s_s - s_a$, difference between entropy of moist air *at saturation*, per pound of dry air, and specific entropy of dry air itself, Btu/lb of dry air·°R, at same pressure and temperature.

s_s = entropy of moist air *at saturation* per pound of dry air, Btu/lb of dry air·°R.

s_w = specific entropy of condensed water (liquid or solid) in equilibrium with saturated air, Btu/lb of water·°R; s_w differs from entropy of pure water at saturation pressure, similar to h_w.

p_s = vapor pressure of water in saturated moist air, in. Hg. Pressure p_s differs negligibly from saturation vapor pressure of pure water p_{ws} at least for conditions shown. Consequently, values of p_s can be used at same pressure and temperature in equations where p_{ws} appears. Pressure p_s is defined as $p_s = x_{ws}p$, where x_{ws} is mole fraction of water vapor in moist air saturated with water at temperature t and pressure p, and where p is total barometric pressure of moist air.

THERMODYNAMIC PROPERTIES OF WATER AT SATURATION

Table 3 shows thermodynamic properties of water at saturation for temperatures from −80 to 300 °F, calculated by the formulations described by Hyland and Wexler (1983b). Symbols in the table follow standard steam table nomenclature. These properties are based on the thermodynamic temperature scale. The enthalpy and entropy of saturated liquid water are both assigned the value zero at the triple point, 32.018 °F. Between the triple-point and critical-point temperatures of water, two states—liquid and vapor—may coexist in equilibrium. These states are called saturated liquid and saturated vapor.

In determining a number of moist air properties, principally the saturation humidity ratio, the *water vapor saturation pressure* is required. Values may be obtained from Table 3 or calculated from the following formulas (Hyland and Wexler 1983b).

The saturation pressure over *ice* for the temperature range of −148 to 32 °F is given by:

$$\ln(p_{ws}) = C_1/T + C_2 + C_3T + C_4T^2 + C_5T^3 + C_6T^4 + C_7\ln(T) \quad (3)$$

where

C_1 = −1.021 416 5 E+04
C_2 = −4.893 242 8 E+00
C_3 = −5.376 579 4 E−03
C_4 = 1.920 237 7 E−07
C_5 = 3.557 583 2 E−10
C_6 = −9.034 468 8 E−14
C_7 = 4.163 501 9 E+00

The saturation pressure over *liquid water* for the temperature range of 32 to 392 °F is given by:

$$\ln(p_{ws}) = C_8/T + C_9 + C_{10}T + C_{11}T^2 + C_{12}T^3 + C_{13}\ln(T) \quad (4)$$

where

C_8 = −1.044 039 7 E+04
C_9 = −1.129 465 0 E+01
C_{10} = −2.702 235 5 E−02
C_{11} = 1.289 036 0 E−05
C_{12} = −2.478 068 1 E−09
C_{13} = 6.545 967 3

In both Equations (3) and (4),

ln = natural logarithm
p_{ws} = saturation pressure, psia
T = absolute temperature, °R = °F + 459.67

The coefficients of Equations (3) and (4) have been derived from the Hyland-Wexler equations, which are given in SI units. Due to rounding errors in the derivations and in some computers' calculating precision, the results obtained from Equations (3) and (4) may not agree precisely with Table 3 values.

HUMIDITY PARAMETERS

Humidity ratio (alternatively, the moisture content or mixing ratio) W of a given moist air sample is defined as the ratio of the mass of water vapor to the mass of dry air contained in the sample:

$$W = M_w/M_a \quad (5)$$

The humidity ratio W is equal to the mole fraction ratio x_w/x_a multiplied by the ratio of molecular masses; namely, 18.01528/28.9645 = 0.62198, *i.e.*:

$$W = 0.62198x_w/x_a \quad (6)$$

Specific humidity q is the ratio of the mass of water vapor to the total mass of the moist air sample:

$$q = M_w/(M_w + M_a) \tag{7a}$$

In terms of the humidity ratio:

$$q = W/(1 + W) \tag{7b}$$

Absolute humidity (alternatively, water vapor density) d_v is the ratio of the mass of water vapor to the total volume of the sample:

$$d_v = M_w/V \tag{8}$$

The *density* ρ of a moist air mixture is the ratio of the total mass to the total volume:

$$\rho = (M_a + M_w)/V = (1/v)(1 + W) \tag{9}$$

where v is the moist air specific volume, ft^3/lb dry air, as defined by Equation (25).

HUMIDITY PARAMETERS INVOLVING SATURATION

The following definitions of humidity parameters involve the concept of moist air saturation:

Saturation humidity ratio $W_s(t, p)$ is the humidity ratio of moist air saturated with respect to water (or ice) at the same temperature t and pressure p.

Degree of saturation μ is the ratio of the air humidity ratio W to the humidity ratio W_s of saturated air at the same temperature and pressure:

$$\mu = \left.\frac{W}{W_s}\right|_{t,p} \tag{10}$$

Relative humidity ϕ is the ratio of the mole fraction of water vapor x_w in a given moist air sample to the mole fraction x_{ws} in an air sample, saturated at the same temperature and pressure:

$$\phi = \left.\frac{x_w}{x_{ws}}\right|_{t,p} \tag{11}$$

Combining Equations (6), (10), and (11):

$$\mu = \frac{\phi}{1 + (1 - \phi)W_s/0.62198} \tag{12}$$

Dew-point temperature t_d is the temperature of moist air saturated at the same pressure p, with the same humidity ratio W as that of the given sample of moist air. It is defined as the solution $t_d(p, W)$ of the equation:

$$W_s(p, t_d) = W \tag{13}$$

Thermodynamic wet-bulb temperature t^* is the temperature at which water (liquid or solid), by evaporating into moist air at a given dry-bulb temperature t and humidity ratio W, can bring air to saturation adiabatically at the same temperature t^* while the pressure p is maintained constant. This parameter is considered separately in a later section.

PERFECT GAS RELATIONSHIPS FOR DRY AND MOIST AIR

When moist air is considered a mixture of independent perfect gases, dry air, and water vapor, each is assumed to obey the perfect gas equation of state as follows:

$$\text{Dry air } p_a V = n_a RT \tag{14}$$

$$\text{Water vapor } p_w V = n_w RT \tag{15}$$

where

p_a = partial pressure of dry air
p_w = partial pressure of water vapor
V = total mixture volume
n_a = number of moles of dry air
n_w = number of moles of water vapor
R = universal gas constant 1545.32 ft · lb_f/lb mol · °R
T = absolute temperature, °R

The mixture also obeys the perfect gas equation:

$$pV = nRT \tag{16}$$

or

$$(p_a + p_w)V = (n_a + n_w)RT \tag{17}$$

where $p = p_a + p_w$ is the total mixture pressure and $n = n_a + n_w$ is the total number of moles in the mixture. From Equations (14) through (17), the mole fractions of dry air and water vapor are, respectively:

$$x_a = p_a/(p_a + p_w) = p_a/p \tag{18}$$

and

$$x_w = p_w/(p_a + p_w) = p_w/p \tag{19}$$

From Equations (6), (18), and (19), the *humidity ratio* W is given by:

$$W = 0.62198\frac{p_w}{p - p_w} \tag{20}$$

The degree of saturation μ is, by definition, Equation (10):

$$\mu = \left.\frac{W}{W_s}\right|_{t,p}$$

where

$$W_s = 0.62198\frac{p_{ws}}{p - p_{ws}} \tag{21}$$

The term p_{ws} represents the saturation pressure of water vapor in the absence of air at the given temperature t. This pressure p_{ws} is a function only of temperature and differs slightly from the vapor pressure of water in saturated moist air.

The *relative humidity* ϕ is, by definition, Equation (11):

$$\phi = \left.\frac{x_w}{x_{ws}}\right|_{t,p}$$

Substituting Equation (19) for x_w and x_{ws}:

$$\phi = \left.\frac{p_w}{p_{ws}}\right|_{t,p} \tag{22}$$

Substituting Equation (19) for x_{ws} into Equation (12):

$$\phi = \frac{\mu}{1 - (1 - \mu)(p_{ws}/p)} \tag{23}$$

Both ϕ and μ are zero for dry air and unity for saturated moist air. At intermediate states their values differ, substantially so at higher temperatures.

The *specific volume* v of a moist air mixture is expressed in terms of a unit mass of dry air, *i.e.*:

$$v = V/M_a = V/(28.9645n_a) \tag{24}$$

where V is the total volume of the mixture, M_a is the total mass of dry air, and n_a is the number of moles of dry air. By Equations (14) and (24), with the relation $p = p_a + p_w$:

$$v = \frac{RT}{28.9645(p - p_w)} = \frac{R_a T}{(p - p_w)} \tag{25}$$

Using Equation (20):

$$v = \frac{RT(1 + 1.6078W)}{28.9645p} = \frac{R_a T(1 + 1.6078W)}{p} \tag{26}$$

In Equations (25) and (26), v is specific volume, T is absolute temperature, p is total pressure, p_w is the partial pressure of water vapor, and W is the humidity ratio.

The *enthalpy* of a mixture of perfect gases equals the sum of the individual partial enthalpies of the components. Therefore, the enthalpy of moist air can be written:

$$h = h_a + Wh_g \tag{27}$$

where h_a is the specific enthalpy for dry air and h_g is the specific enthalpy for saturated water vapor at the temperature of the mixture. Approximately:

$$h_a = 0.240t \quad \text{(Btu/lb)} \tag{28}$$

$$h_g = 1061 + 0.444t \quad \text{(Btu/lb)} \tag{29}$$

where t is the dry-bulb temperature, °F. The moist air enthalpy then becomes:

$$h = 0.240t + W(1061 + 0.444t) \quad \text{(Btu/lb)} \tag{30}$$

THERMODYNAMIC WET-BULB TEMPERATURE AND DEW-POINT TEMPERATURE

For any state of moist air, a temperature t^* exists at which liquid (or solid) water evaporates into the air to bring it to saturation at exactly this same temperature and pressure (Harrison 1965). During the adiabatic saturation process, the saturated air is expelled at a temperature equal to that of the injected water (Figures 8 and 9). In the constant pressure process, the humidity ratio is increased from a given initial value W to the value W_s^*, corresponding to saturation at the temperature t^*; the enthalpy is increased from a given initial value h to the value h_s^*, corresponding to saturation at the temperature t^*; the mass of water added per unit mass of dry air is $(W_s^* - W)$, which adds energy to the moist air of amount $(W_s^* - W)h_w^*$, where h_w^* denotes the specific enthalpy of the water added at the temperature t^*. Therefore, if the process is strictly adiabatic, conservation of enthalpy at constant pressure requires that:

$$h + (W_s^* - W)\, h_w^* = h_s^* \tag{31}$$

The properties W_s^*, h_w^*, and h_s^* are functions only of the temperature t^* for a fixed value of pressure. The value of t^*, which satisfies Equation (31) for given values of h, W, and p, is the *thermodynamic wet-bulb temperature.*

The *psychrometer* consists of two thermometers; one thermometer's bulb is covered by a wick that has been thoroughly wetted with water. When the wet bulb is placed in an airstream, water evaporates from the wick, eventually reaching an equilibrium temperature called the *wet-bulb temperature.* This process is not one of adiabatic saturation, which defines the thermodynamic wet-bulb temperature, but is one of simultaneous heat and mass transfer from the wet bulb. The fundamental mechanism of this process is described by the Lewis relation (Chapter 5). Fortunately, only small corrections must be applied to wet-bulb thermometer readings to obtain the thermodynamic wet-bulb temperature.

As defined, thermodynamic wet-bulb temperature is a unique property of a given moist air sample independent of measurement techniques. Chapter 5 of the ASHRAE *Brochure on Psychrometry* (1977) discusses the concept in more detail.

Equation (31) is exact since it defines the thermodynamic wet-bulb temperature t^*. Substituting the approximate perfect gas relation [Equation (30)] for h, the corresponding expression for h_s^*, and the approximate relation

$$h_w^* = t^* - 32 \quad \text{(Btu/lb)} \tag{32}$$

into Equation (31), and solving for the humidity ratio:

$$W = \frac{(1093 - 0.556t^*)W_s^* - 0.240(t - t^*)}{1093 + 0.444t - t^*} \tag{33}$$

where t and t^* are in °F.

The *dew-point temperature* t_d of moist air with humidity ratio W and pressure p was defined earlier as the solution $t_d(p, w)$ of $W_s(p, t_d) = W$. For perfect gases, this reduces to:

$$p_{ws}(t_d) = p_w = (pW)/(0.62198 + W) \tag{34}$$

where p_w is the water vapor partial pressure for the moist air sample and $p_{ws}(t_d)$ is the saturation vapor pressure at temperature t_d. The saturation vapor pressure is derived from Table 3 or from Equations (3) or (4). Alternatively, the dew-point temperature can be calculated directly by one of the following equations (Peppers 1988):

For the dew-point temperature range of 32 to 200 °F:

$$t_d = C_{14} + C_{15}\alpha + C_{16}\alpha^2 + C_{17}\alpha^3 + C_{18}(p_w)^{0.1984} \tag{35}$$

and for temperatures below 32 °F:

$$t_d = 90.12 + 26.412\alpha + 0.8927\alpha^2 \tag{36}$$

where

t_d = dew-point temperature, °F
α = ln (p_w)
p_w = water vapor partial pressure, psia
C_{14} = 100.45
C_{15} = 33.193
C_{16} = 2.319
C_{17} = 0.17074
C_{18} = 1.2063

NUMERICAL CALCULATION OF MOIST AIR PROPERTIES

The following are outlines, citing equations and tables already presented, for calculating moist air properties using perfect gas relations. These relations are sufficiently accurate for most engineering calculations in air-conditioning practice, and are readily adapted to either hand or computer calculating methods. Graphical procedures are discussed in the section on psychrometric charts.

Situation 1. Given: Dry-bulb temperature t
Wet-bulb temperature t^*
Pressure p

To Obtain	Use	Comments
$p_{ws}(t^*)$	Table 3 or Eq. (3) or (4)	Sat. press. for temp. t^*
W_s^*	Eq. (21)	Using $p_{ws}(t^*)$
W	Eq. (33)	
$p_{ws}(t)$	Table 3 or Eq. (3) or (4)	Sat. press. for temp. t
W_s	Eq. (21)	Using $p_{ws}(t)$
μ	Eq. (10)	Using W_s
ϕ	Eq. (23)	Using $p_{ws}(t)$
v	Eq. (26)	
h	Eq. (30)	
p_w	Eq. (34)	
t_d	Table 3 with Eq. (34), (35), or (36)	

Situation 2. Given: Dry-bulb temperature t
Dew-point temperature t_d
Pressure p

To Obtain	Use	Comments
$p_w = p_{ws}(t_d)$	Table 3 or Eq. (3) or (4)	Sat. press. for temp. t_d
W	Eq. (20)	
$p_{ws}(t)$	Table 3 or Eq. (3) or (4)	Sat. press. for temp. t_d
W_s	Eq. (21)	Using $p_{ws}(t)$
μ	Eq. (10)	Using W_s
ϕ	Eq. (23)	Using $p_{ws}(t)$
v	Eq. (26)	
h	Eq. (30)	
t^*	Eq. (21) and (33) with Table 3 or with Eq. (3) or (4)	Requires trial-and-error or numerical solution method

Situation 3. Given: Dry-bulb temperature t
Relative humidity ϕ
Pressure p

To Obtain	Use	Comments
$p_{ws}(t)$	Table 3 or Eq. (3) or (4)	Sat. press. for temp. t
p_w	Eq. (22)	
W	Eq. (20)	
W_s	Eq. (21)	Using $p_{ws}(t)$
μ	Eq. (10)	Using W_s
v	Eq. (26)	
h	Eq. (30)	
t_d	Table 3 with Eq. (34), (35), or (36)	
t^*	Eq. (21) and (33) with Table 3 or with Eq. (3) or (4)	Requires trial-and-error or numerical solution method

EXACT RELATIONS FOR COMPUTING W_s AND ϕ

Corrections that account for (1) the effect of dissolved gases on properties of condensed phase; (2) the effect of pressure on properties of condensed phase; and (3) the effect of intermolecular force on properties of moisture itself, can be applied to Equations (21) or (23):

$$W_s = 0.62198[f_s p_{ws}/(p - f_s p_{ws})] \quad (21a)$$

$$\phi = \frac{\mu}{1 - (1 - \mu)(f_s p_{ws}/p)} \quad (23a)$$

Table 4 lists f_s values for a number of pressure and temperature combinations. Hyland and Wexler (1983a) give additional values.

Table 4 Values of f_s and Estimated Maximum Uncertainties (EMU)

	14.50 psia		72.52 psia		145.04 psia	
T, °R	f	EMU E+04	f	EMU E+04	f	EMU E+04

491.67	1.0039	2	1.0177	10	1.0353	19
671.67	1.0039	0.1	1.0180	4	1.0284	11

MOIST AIR PROPERTY TABLES FOR STANDARD PRESSURE

Table 2 shows values of thermodynamic properties for standard atmospheric pressure at temperatures from −80 to 200 °F. The properties of intermediate moist air states can be calculated using the degree of saturation μ:

$$\text{Volume} \quad v = v_a + \mu v_{as} \quad (37)$$

$$\text{Enthalpy} \quad h = h_a + \mu h_{as} \quad (38)$$

$$\text{Entropy} \quad s = s_a + \mu s_{as} \quad (39)$$

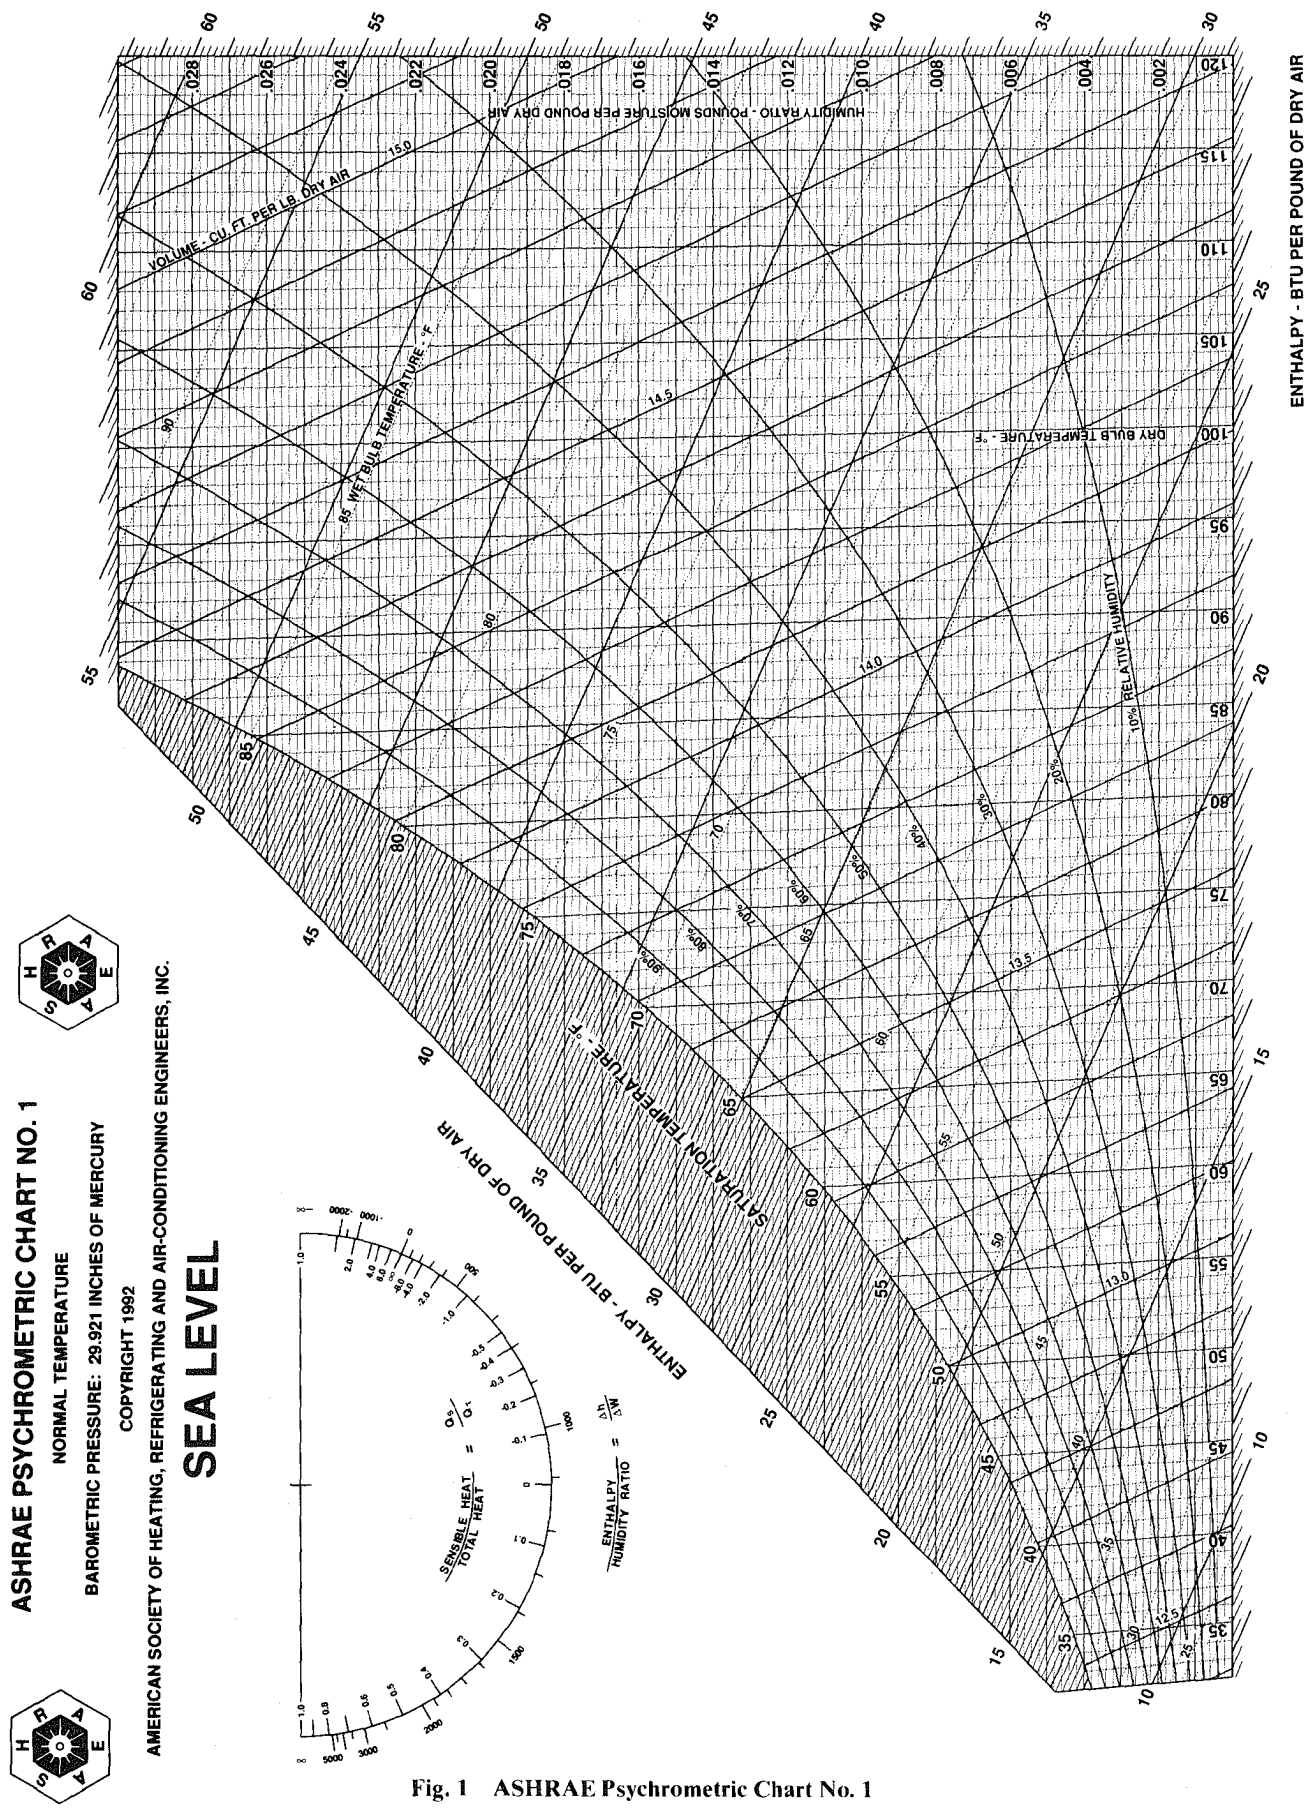
These equations are accurate to about 160 °F. At higher temperatures, the errors can be significant. Hyland and Wexler (1983a) include charts that can be used to estimate errors for v, h, and s for standard barometric pressure.

PSYCHROMETRIC CHARTS

A psychrometric chart graphically represents the thermodynamic properties of moist air.

The choice of coordinates for a psychrometric chart is arbitrary. A chart with coordinates of enthalpy and humidity ratio provides convenient graphical solutions of many moist air problems with a minimum of thermodynamic approximations. ASHRAE developed seven such psychrometric charts.

Charts 1, 2, and 3 are for sea level pressure. Chart 4 is for 5000-ft altitude (24.89 in. Hg). Chart 5 is for 7500-ft altitude (22.65 in. Hg). All charts use oblique-angle coordinates of enthalpy and humidity ratio, and are consistent with the data of Table 2 and the properties computation methods of Goff and Gratch (1945, 1949) as well as Hyland and Wexler (1983a). Palmatier (1963) describes the geometry of chart construction applying specifically to Charts 1 and 4.



ASHRAE PSYCHROMETRIC CHART NO. 1
NORMAL TEMPERATURE
BAROMETRIC PRESSURE: 29.921 INCHES OF MERCURY

WET BULB TEMPERATURE - °F
RELATIVE HUMIDITY
SENSIBLE HEAT / TOTAL HEAT
ENTHALPY / HUMIDITY RATIO

Fig. 1 ASHRAE Psychrometric Chart No. 1

The dry-bulb temperature ranges covered by the charts are:

Charts 1, 4, 5	Normal temperature	32 to 120°F
Chart 2	Low temperature	−40 to 50°F
Chart 3	High temperature	60 to 250°F

Charts 1 and 4 are constructed on the identical system of coordinates. Psychrometric properties or charts for other barometric pressures can be derived by interpolation. Sufficiently exact values for most purposes can be derived by methods described in the section on perfect gas relations. The construction of charts for altitude conditions has been treated by Haines (1961), Rohsenow (1946), and Karig (1946).

Comparison of Charts 1 and 4 by overlay reveals:

1. The dry-bulb lines coincide.
2. Wet-bulb lines for a given temperature originate at the intersections of the corresponding dry-bulb line and the two saturation curves, and they have the same slope.
3. Humidity ratio and enthalpy for a given dry- and wet-bulb increase with altitude, but there is little change in relative humidity.
4. Volume changes rapidly; for a given dry-bulb and humidity ratio, it is practically inversely proportional to barometric pressure.

The following table compares properties at sea level (Chart 1) and 5000-ft (Chart 4):

Chart No.	db	wb	h	W	rh	v
1	100	81	44.6	0.0186	45	14.5
4	100	81	49.8	0.0234	46	17.6

Figure 1, which is Chart 1 of the ASHRAE psychrometric charts, shows humidity ratio lines (horizontal) for the range from 0 (dry air) to 0.03 lb water/lb dry air. Enthalpy lines are oblique lines drawn across the chart precisely parallel to each other.

Dry-bulb temperature lines are drawn straight, not precisely parallel to each other, and inclined slightly from the vertical position. Thermodynamic wet-bulb temperature lines are oblique lines that differ slightly in direction from that of enthalpy lines. They are identically straight but are not precisely parallel to each other.

Relative humidity (rh) lines are shown in intervals of 10%. The saturation curve is the line of 100% rh, while the horizontal line for $W = 0$ (dry air) is the line for 0% rh.

Specific volume lines are straight but are not precisely parallel to each other.

A narrow region above the saturation curve has been developed for fog conditions of moist air. This two-phase region represents a mechanical mixture of saturated moist air and liquid water, with the two components in thermal equilibrium. Isothermal lines in the fog region coincide with extensions of thermodynamic wet-bulb temperature lines. If required, the fog region can be further expanded by extension of humidity ratio, enthalpy, and thermodynamic wet-bulb temperature lines.

The protractor to the left of the chart shows two scales—one for sensible-total heat ratio, and one for the ratio of enthalpy difference to humidity ratio difference. The protractor is used to establish the direction of a condition line on the psychrometric chart. The full-size charts available from ASHRAE include a nomograph that provides an alternate method for determining enthalpy from the psychrometric chart, and allows a direct reading of the enthalpy $\Delta W h_w$ of liquid water added or rejected in a process.

Example 1 illustrates use of the ASHRAE psychrometric chart to determine moist air properties.

Example 1. Moist air exists at 100°F dry-bulb temperature, 65°F thermodynamic wet-bulb temperature, and 29.921 in. Hg pressure. Determine the humidity ratio, enthalpy, dew-point temperature, relative humidity, and volume.

Solution: Locate state point on Chart 1 (Figure 1) at the intersection of 100°F dry-bulb temperature and 65°F thermodynamic wet-bulb temperature lines. Read $W = 0.00523$ lb water/lb dry air.

The enthalpy can be found by two methods. Using two triangles, draw a line parallel to the nearest enthalpy line (30 Btu/lb dry air) through the state point to the nearest edge scale. Read $h = 29.80$ Btu/lb dry air.

Enthalpy can also be derived from Equation (31):

$$h = h_s^* - (W_s^* - W)h_w^*$$

where $(W_s^* - W)h_w^* = D$, the enthalpy deviation given by the nomograph, and h_s^* is the enthalpy of saturated moist air at the thermodynamic wet-bulb temperature at 65°F, read $h_s^* = 30.06$ Btu/lb of dry air. By nomograph, at $W = 0.00523$ lb water/dry air and $t^* = 65$°F, read $D = -0.26$ Btu/lb dry air. Thus, $h = 30.06 - 0.26 = 29.80$ Btu/lb dry air.

Dew-point temperature can be read at the intersection of $W = 0.00523$ lb water/lb dry air with the saturation curve. Thus, $t_d = 40$°F.

Relative humidity ϕ can be estimated directly. Thus, $\phi = 13\%$.

Volume can be found by linear interpolation between the volume lines for 14.0 and 14.5 ft³/lb dry air. Thus, $v = 14.22$ ft³/lb dry air.

TYPICAL AIR-CONDITIONING PROCESSES

The ASHRAE psychrometric chart can be used to solve numerous process problems with moist air. Its use is best explained through illustrative examples. In each of the following examples, the process takes place at a constant pressure of 29.921 in. Hg.

Moist Air Heating

The process of adding heat alone to moist air is represented by a horizontal line on the ASHRAE chart, since the humidity ratio remains unchanged.

Figure 2 shows a device that adds heat to a stream of moist air. For steady flow conditions, the required rate of heat addition is:

$$_1q_2 = m_a(h_2 - h_1) \qquad (40)$$

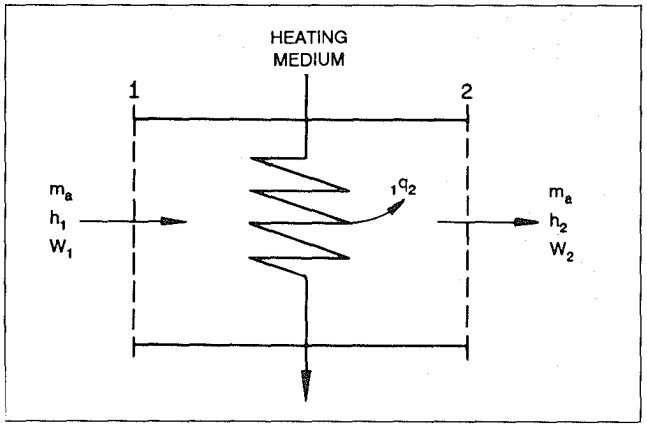

Fig. 2 Schematic Device for Heating Moist Air

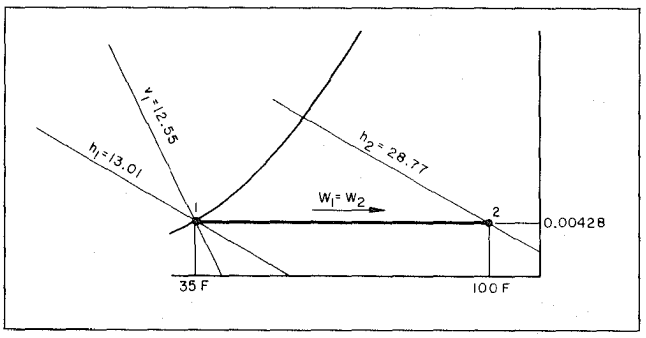

Fig. 3 Schematic Solution for *Example 2*

Example 2. Moist air, saturated at 35 °F, enters a heating coil at a rate of 20,000 cfm. Air leaves the coil at 100 °F. Find the required rate of heat addition in Btu/h.

Solution: Figure 3 schematically shows the solution. State 1 is located on the saturation curve at 35 °F. Thus, $h_1 = 13.01$ Btu/lb dry air, $W_1 = 0.00428$ lb water/lb dry air, and $v_1 = 12.55$ ft^3/lb dry air. State 2 is located at the intersection of $t = 100$°F and $W_2 = W_1 = 0.00428$ lb water/lb dry air. Thus, $h_2 = 28.77$ Btu/lb dry air. The mass flow of dry air is:

$$m_a = [(20{,}000)(60)/12.55] = 95{,}620 \text{ lb dry air/h}$$

From Equation (40):

$$_1q_2 = (95{,}620)(28.77 - 13.01) = 1{,}507{,}000 \text{ Btu/h}$$

Moist Air Cooling

Moisture separation occurs when moist air is cooled to a temperature below its initial dew point. Figure 4 shows a schematic cooling coil where moist air is assumed to be uniformly processed. Although water can be separated at various temperatures ranging from the initial dew point to the final saturation temperature, it is assumed that condensed water is cooled to the final air temperature t_2 before it drains from the system.

For the system of Figure 4, the steady flow energy and material balance equations are:

$$m_a h_1 = m_a h_2 + {}_1q_2 + m_w h_{w2}$$
$$m_a W_1 = m_a W_2 + m_w$$

Thus:

$$m_w = m_a(W_1 - W_2) \quad (41)$$
$$_1q_2 = m_a[(h_1 - h_2) - (W_1 - W_2)h_{w2}] \quad (42)$$

Example 3. Moist air at 85 °F dry-bulb temperature and 50% rh enters a cooling coil at 10,000 cfm and is processed to a final saturation condition at 50 °F. Find the tons of refrigeration required.

Solution: Figure 5 shows the schematic solution. State 1 is located at the intersection of $t = 85$ °F and $\phi = 50\%$. Thus, $h_1 = 34.62$ Btu/lb dry air, $W_1 = 0.01292$ lb water/lb dry air, and $v_1 = 14.01$ ft^3/lb dry air. State 2 is located on the saturation curve at 50 °F. Thus, $h_2 = 20.30$ Btu/lb dry air and $W_2 = 0.00766$ lb water/lb dry air. From Table 2, $h_{w2} = 18.11$ Btu/lb water. The mass flow of dry air is:

$$m_a = 10{,}000/14.01 = 713.8 \text{ lb dry air/min}$$

From Equation (42):

$$_1q_2 = 713.8[(34.62 - 20.30) - (0.01292 - 0.00766)(18.11)]$$
$$= 10{,}150 \text{ Btu/min}$$

Since one ton of refrigeration equals a heat withdrawal of 200 Btu/min, the required refrigerating capacity is 50.75 tons.

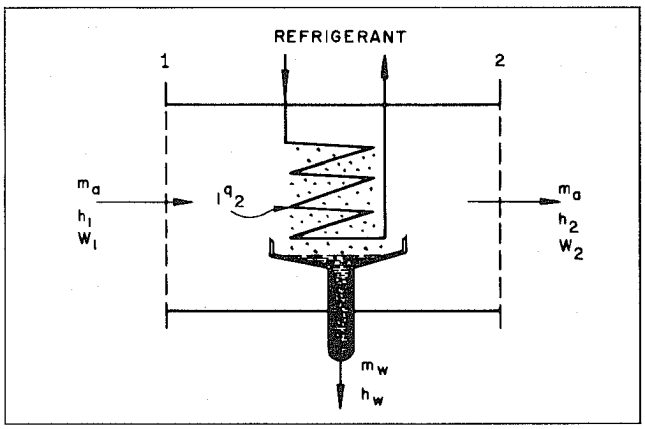

Fig. 4 Schematic Device for Cooling Moist Air

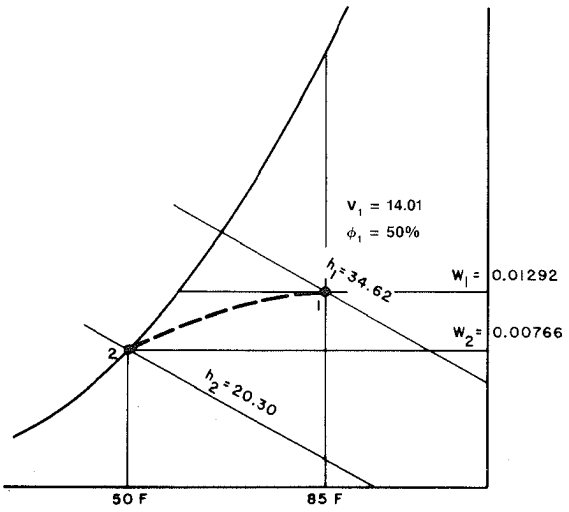

Fig. 5 Schematic Solution for *Example 3*

Adiabatic Mixing of Two Moist Airstreams

A common process in air-conditioning systems is the adiabatic mixing of two moist airstreams. Figure 6 schematically shows the problem. Adiabatic mixing is governed by three equations:

$$m_{a1}h_1 + m_{a2}h_2 = m_{a3}h_3$$
$$m_{a1} + m_{a2} = m_{a3}$$
$$m_{a1}W_1 + m_{a2}W_2 = m_{a3}W_3$$

Eliminating m_{a3} gives:

$$\frac{h_2 - h_3}{h_3 - h_1} = \frac{W_2 - W_3}{W_3 - W_1} = \frac{m_{a1}}{m_{a2}} \quad (43)$$

according to which, on the ASHRAE chart, the state point of the resulting mixture lies on the straight line connecting the state points of the two streams being mixed, and divides the line into two segments, in the same ratio as the masses of dry air in the two streams.

Example 4. A stream of 5000 cfm of outdoor air at 40 °F dry-bulb temperature and 35 °F thermodynamic wet-bulb temperature is adiabatically mixed with 15,000 cfm of recirculated air at 75 °F dry-bulb temperature and 50% rh. Find the dry-bulb temperature and thermodynamic wet-bulb temperature of the resulting mixture.

Solution: Figure 7 shows the schematic solution. States 1 and 2 are located on the ASHRAE chart, revealing that $v_1 = 12.65$ ft^3/lb dry air, and $v_2 = 13.68$ ft^3/lb dry air. Therefore:

$$m_{a1} = 5000/12.65 = 395 \text{ lb dry air/min}$$
$$m_{a2} = 15{,}000/13.68 = 1096 \text{ lb dry air/min}$$

According to Equation (43):

$$\frac{\text{Line 3—2}}{\text{Line 1—3}} = \frac{m_{a1}}{m_{a2}} \quad \text{or} \quad \frac{\text{Line 1—3}}{\text{Line 1—2}} = \frac{m_{a2}}{m_{a3}} = \frac{1096}{1491} = 0.735$$

Consequently, the length of line segment 1—3 is 0.735 times the length of entire line 1—2. Using a ruler, State 3 is located, and the values $t_3 = 65.9$ °F and $t_3{}^* = 56.6$ °F found.

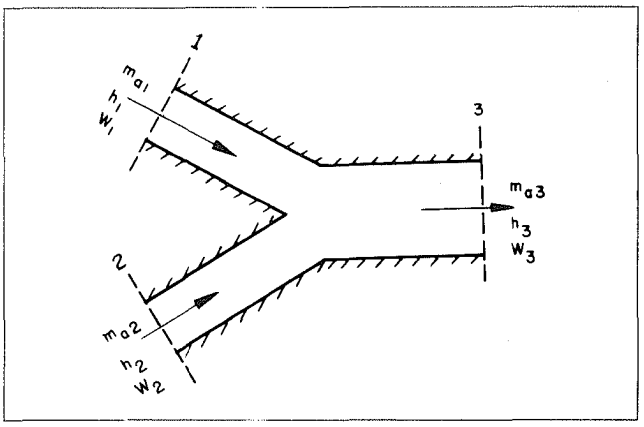

Fig. 6 Adiabatic Mixing of Two Moist Airstreams

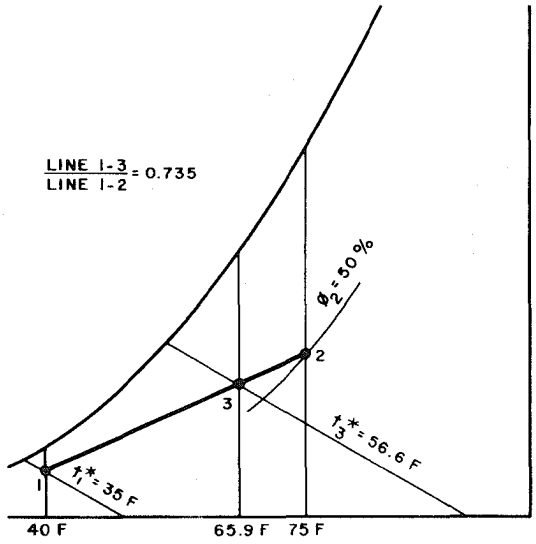

Fig. 7 Schematic Solution for *Example 4*

Adiabatic Mixing of Water Injected into Moist Air

Steam or liquid water can be injected into a moist airstream to raise its humidity. Figure 8 represents a diagram of this common air-conditioning process. If the mixing is adiabatic, the following equations apply:

$$m_a h_1 + m_w h_w = m_a h_2$$
$$m_a W_1 + m_w = m_a W_2$$

Therefore,

$$\frac{h_2 - h_1}{W_2 - W_1} = h_w \qquad (44)$$

according to which, on the ASHRAE chart, the final state point of the moist air lies on a straight line whose direction is fixed by the specific enthalpy of the injected water, drawn through the initial state point of the moist air.

Example 5. Moist air at 70 °F dry-bulb and 45 °F thermodynamic wetbulb temperature is to be processed to a final dew-point temperature of 55 °F by adiabatic injection of saturated steam at 230 °F. The rate of dry airflow is 200 lb/min. Find the final dry-bulb temperature of the moist air and the rate of steam flow required in lb/h.

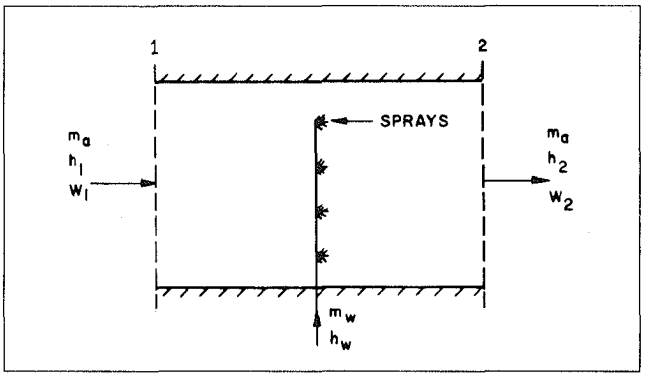

Fig. 8 Schematic Injection of Water into Moist Air

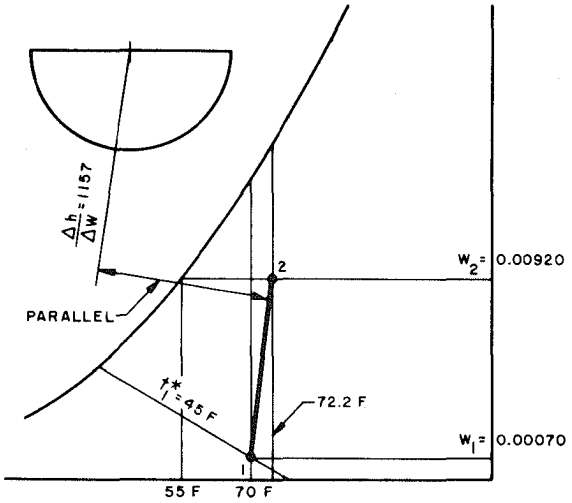

Fig. 9 Schematic Solution for *Example 5*

Solution: Figure 9 shows the schematic solution. By Table 3, the enthalpy of the steam h_g = 1157 Btu/lb water. Therefore, according to Equation (44), the condition line on the ASHRAE chart connecting States 1 and 2 must have a direction:

$$\Delta h/\Delta W = 1157 \text{ Btu/lb water}$$

The condition line can be drawn with the $\Delta h/\Delta W$ protractor. First, establish the reference line on the protractor by connecting the origin with the value $\Delta h/\Delta W$ = 1157. Draw a second line parallel to the reference line and through the initial state point of the moist air. This second line is the condition line. State 2 is established at the intersection of the condition line with the horizontal line extended from the saturation curve at 55 °F (t_{d2} = 55 °F). Thus, t_2 = 72.2 °F.

Values of W_2 and W_1 can be read from the chart. The required steam flow is:

$$m_w = m_a(W_2 - W_1) = (200)(60)(0.00920 - 0.00070)$$
$$= 102 \text{ lb steam/h}$$

Space Heat Absorption and Moist Air Moisture Gains

The problem of air conditioning a space is usually determined by (1) the quantity of moist air to be supplied, and (2) the air condition necessary to remove given amounts of energy and water from the space and be withdrawn at a specified condition.

Figure 10 schematically shows a space with incident rates of energy and moisture gains. The quantity q_s denotes the net sum of all rates of heat gain in the space, arising from transfers through

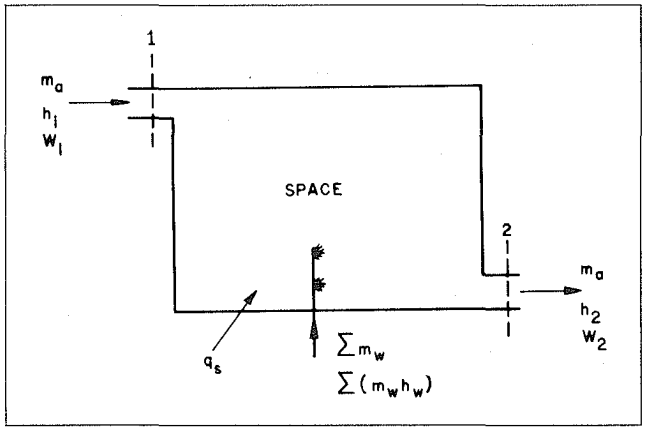

Fig. 10 Schematic Problem of Air Conditioning a Space

boundaries and from sources within the space. This heat gain involves addition of energy alone and does not include energy contributions due to addition of water (or water vapor). It is usually called the *sensible heat gain.* The quantity Σm_w denotes the net sum of all rates of moisture gain on the space arising from transfers through boundaries and from sources within the space. Each pound of moisture injected into the space adds an amount of energy equal to its specific enthalpy.

Assuming steady-state conditions, governing equations are:

$$m_a h_1 + q_s + \Sigma(m_w h_w) = m_a h_2$$
$$m_a W_1 + \Sigma m_w = m_a W_2$$

or

$$q_s + \Sigma(m_w h_w) = m_a(h_2 - h_1) \quad (45)$$
$$\Sigma m_w = m_a(W_2 - W_1) \quad (46)$$

The left side of Equation (45) represents the total rate of energy addition to the space from all sources. By Equations (45) and (46):

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{q_s + \Sigma(m_w h_w)}{\Sigma m_w} \quad (47)$$

according to which, on the ASHRAE chart and for a given state of the withdrawn air, all possible states (conditions) for the supply air must lie on a straight line drawn through the state point of the withdrawn air, that has a direction specified by the numerical value of $[q_s + \Sigma(m_w h_w)]/\Sigma m_w$. This line is the condition line for the given problem.

Example 6. Moist air is withdrawn from a room at 80 °F dry-bulb temperature and 66 °F thermodynamic wet-bulb temperature. The sensible rate of heat gain for the space is 30,000 Btu/h. A rate of moisture gain of 10 lb/h occurs from the space occupants. This moisture is assumed as saturated water vapor at 90 °F. Moist air is introduced into the room at a dry-bulb temperature of 60 °F. Find the required thermodynamic wet-bulb temperature and volume flow rate of the supply air.

Solution: Figure 11 shows the schematic solution. State 2 is located on the ASHRAE chart. From Table 3, specific enthalpy of added water vapor is h_g = 1100.40 Btu/lb. From Equation (47):

$$\frac{\Delta h}{\Delta W} = \frac{30{,}000 + (10)(1100.40)}{10} = 4100 \text{ Btu/lb water}$$

With the $\Delta h/\Delta W$ protractor, establish a reference line of direction $\Delta h/\Delta W$ = 4100 Btu/lb water. Parallel to this reference line, draw a straight line on the chart through State 2. The intersection of this line with the 60 °F dry-bulb temperature line is State 1. Thus, t_1^* = 56.4 °F.

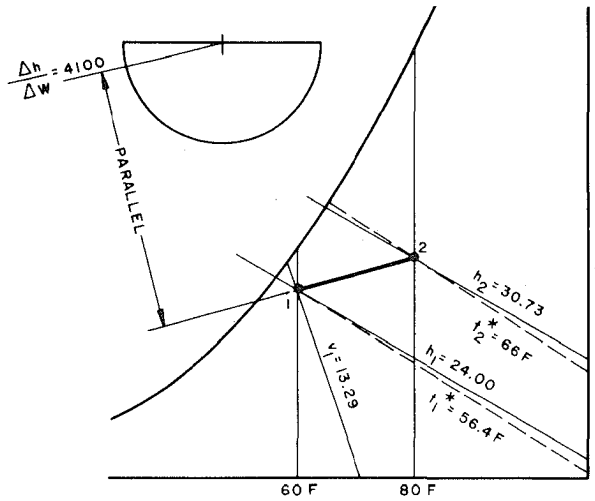

Fig. 11 Schematic Solution for *Example 6*

An alternate (and approximately correct) procedure in establishing the condition line is to use the protractor's sensible-total heat ratio scale instead of the $\Delta h/\Delta W$ scale. The quantity $\Delta H_s/\Delta H_T$ is the ratio of the rate of sensible heat gain for the space to the rate of total energy gain for the space. Therefore:

$$\frac{\Delta H_s}{\Delta H_T} = \frac{q_s}{q_s + \Sigma(m_w h_w)} = \frac{30{,}000}{30{,}000 + (10 \times 1100.44)} = 0.732$$

Note that $\Delta H_s/\Delta H_T$ = 0.732 on the protractor coincides closely with $\Delta h/\Delta W$ = 4100 Btu/lb water.

The flow rate of dry air can be calculated from either Equation (45) or (46). From Equation (45):

$$m_a = \frac{q_s + \Sigma(m_w h_w)}{h_2 - h_1} = \frac{30{,}000 + (10 \times 1100.44)}{(60)(30.73 - 24.00)}$$
$$= 101.5 \text{ lb dry air/min}$$

At State 1, v_1 = 13.29 ft³/lb dry air.

Therefore, supply volume = $m_a v_1$ = 101.5 × 13.29 = 1349 cfm

TRANSPORT PROPERTIES OF MOIST AIR

For certain scientific and experimental work, particularly in the heat transfer field, many other moist air properties are important. Generally classified as transport properties, these include diffusion coefficient, viscosity, thermal conductivity, and thermal diffusion factor. Mason and Monchick (1965) derive these properties by calculation. Table 5 and Figures 12 and 13 summarize the

Table 5 Calculated Diffusion Coefficients for Water-Air at 29.921 in. Hg Barometric Pressure

Temp., °F	ft²/h	Temp., °F	ft²/h	Temp., °F	ft²/h
−100	0.504	40	0.884	140	1.205
−50	0.6	50	0.915	150	1.240
−40	0.655	60	0.942	200	1.414
−30	0.682	70	0.973	250	1.600
−20	0.709	80	1.008	300	1.794
−10	0.736	90	1.042	350	1.996
0	0.767	100	1.073	400	2.205
10	0.794	110	1.104	450	2.422

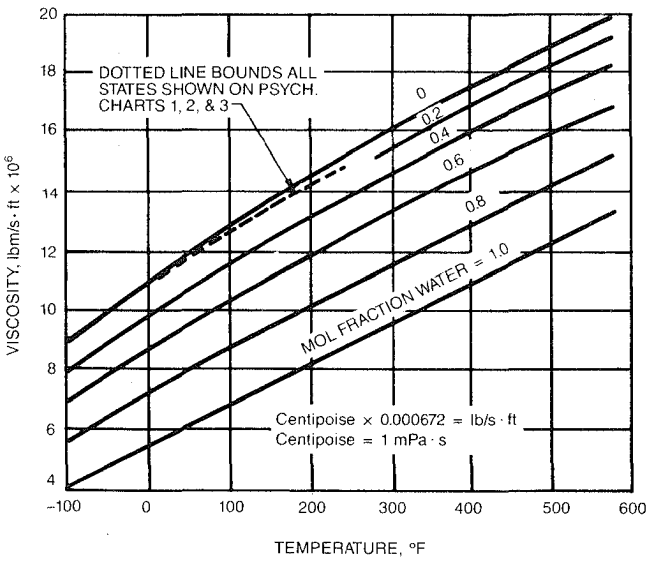

Fig. 12 Viscosity of Moist Air

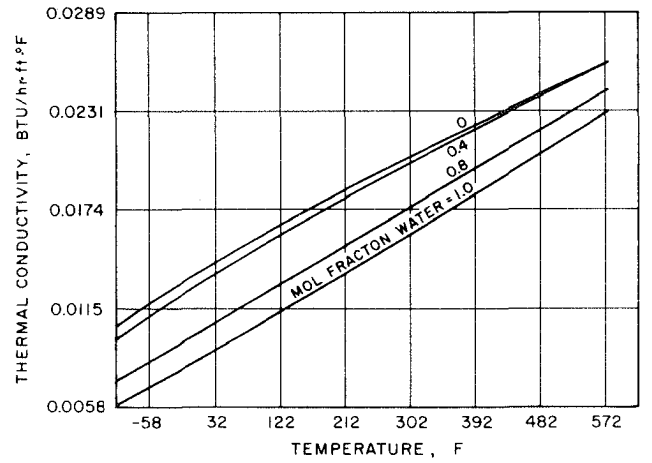

Fig. 13 Thermal Conductivity of Moist Air

author's results on the first three properties listed. Note that, within the boundaries of Charts 1, 2, and 3, the viscosity varies little from that of dry air at normal atmospheric pressure, and the thermal conductivity is essentially identical.

AIR, WATER, AND STEAM PROPERTIES

Coefficient f_w (or f_s) (over water) at pressures from 0.145 to 31.799 in. Hg for temperatures from −58 to 140 °F (Smithsonian Institution).

Coefficient f_i (over ice) at pressures from 0.145 to 31.799 in. Hg for temperatures from 32 to 212 °F (Smithsonian Institution).

Compressibility factor of dry air at pressures from 0.147 to 1470 psi and at temperatures from 90 to 5400 °R (Hilsenrath *et al.* 1960).

Compressibility factor of moist air at pressures from 25 to 31 in. Hg at humidity ratios from 0.006 to 0.30 lb of water per lb of dry air, and for temperatures from 40 to 100 °F. At pressures from 0 to 31.799 in. Hg, at values of degree of saturation from 0 to 100, and for temperatures from 32 to 140 °F (Smithsonian Institution). [Note: At the time the Smithsonian Meteorological Tables were published, the value $\mu = W/W_s$ was known as relative humidity, in terms of a percentage. Since that time, there has been general agreement to designate the value μ as degree of saturation, usually expressed as a decimal and sometimes as a percentage. See Goff (1949) for more recent data and formulations.]

Compressibility factor for steam at pressures from 14.696 to 440 psi and at temperatures from 684 to 1530 °R (Hilsenrath *et al.* 1960).

Density, enthalpy, entropy, Prandtl number, specific heat, specific heat ratio, and viscosity of dry air (Hilsenrath *et al.* 1960).

Density, enthalpy, entropy, specific heat, viscosity, thermal conductivity, and free energy of steam (Hilsenrath *et al.* 1960).

Dry air. Thermodynamic properties over a wide range of temperature (Keenan and Kaye 1945).

Enthalpy of saturated steam (Osborne *et al.* 1939).

Ideal-gas thermodynamic functions of dry air at temperatures from 18 to 5400 °R (Hilsenrath *et al.* 1960).

Ideal-gas thermodynamic functions of steam at temperatures from 90 to 9000 °R. Functions included are specific heat, enthalpy, free energy, and entropy (Hilsenrath *et al.* 1960).

Moist air properties from tabulated virial coefficients (Chaddock 1965).

Saturation humidity ratio over ice at pressures from 8.672 to 28.908 in. Hg and for temperatures from −128 to 32 °F (Smithsonian Institution).

Saturation humidity ratio over water at pressures from 1.73 to 30.35 and for temperatures from −58 to 138.2 °F (Smithsonian Institution).

Saturation vapor pressure over water in in. Hg and for temperatures from −60 to 212 °F (Smithsonian Institution).

Speed of sound in dry air at pressures from 0.147 to 1470 psi for temperatures from 90 to 5400 °R (Hilsenrath *et al.* 1960). At atmospheric pressure for temperatures from −130 to 140 °F (Smithsonian Institution).

Speed of sound in moist air. Relations using the formulation of Goff and Gratch and studies by Hardy *et al.* (1942) give methods for calculating this speed (Smithsonian Institution).

Steam tables covering the range from 32 to 1472 °F.

Transport properties of moist air. Diffusion coefficient, viscosity, thermal conductivity, and thermal diffusion factor of moist air are listed (Mason and Monchick 1965). The author's results are summarized in Table 5 and Figures 11 and 12.

Virial coefficients and other information for use with Goff and Gratch formulation (Goff 1949).

Volume of water in cubic feet for temperatures from −14 to 482 °F (Smithsonian Institution 1954).

Water properties. Includes properties of ordinary water substance for the gaseous, liquid, and solid phases (Dorsey 1940).

SYMBOLS

α = $\ln(\rho_w)$, parameter used in Equations (35) and (36)
μ = degree of saturation W/W_s, dimensionless
ρ = moist air density, lb/ft^3
ϕ = relative humidity, dimensionless
C_1 to C_{18} = constants in Equations (3), (4), and (35)
d_v = absolute humidity of moist air, mass of water per unit volume of mixture
D = enthalpy deviation, Btu/lb dry air
f_s = enhancement factor, used in Equations (21a) and (23a)
h = enthalpy of moist air, Btu/lb dry air
h_a = specific enthalpy of dry air, Btu/lb
h_{as} = $h_s - h_a$
h_f = specific enthalpy of saturated liquid water
h_{fg} = $h_g - h_f$
h_g = specific enthalpy of saturated water vapor

h_s = enthalpy of moist air at saturation per unit mass of dry air
h_s^* = enthalpy of moist air at saturation at thermodynamic wet-bulb temperature per unit mass of dry air
h_w = specific enthalpy of water (any phase) added to or removed from moist air in a process
h_w^* = specific enthalpy of condensed water (liquid or solid) at thermodynamic wet-bulb temperature and pressure of 29.921 in. Hg
H_s = rate of sensible heat gain for space
H_t = rate of total energy gain for space
m_a = mass flow of dry air, per unit time
m_w = mass flow of water (any phase), per unit time
M_a = mass of dry air in moist air sample
M_w = mass of water vapor in moist air sample
$n = n_a + n_w$, total number of moles in moist air sample
n_a = moles of dry air
n_w = moles of water vapor
p = total pressure of moist air
p_a = partial pressure of dry air
p_s = vapor pressure of water in moist air at saturation. Differs from saturation pressure of pure water because of presence of air.
p_w = partial pressure of water vapor in moist air
p_{ws} = pressure of saturated pure water
q = specific humidity of moist air, mass of water per unit mass of mixture
q_s = rate of addition (or withdrawal) of sensible heat
R = universal gas constant, 1545.32 $(lb_f/ft^2)ft^3/(lb\ mole \cdot °R)$
R_a = gas constant for dry air
R_w = gas constant for water vapor
s = entropy of moist air per unit mass of dry air
s_a = specific entropy of dry air
$s_{as} = s_s - s_a$
s_f = specific entropy of saturated liquid water
$s_{fg} = s_g - s_f$
s_g = specific entropy of saturated water vapor
s_s = specific entropy of moist air at saturation per unit mass of dry air
s_w = specific entropy of condensed water (liquid or solid) at pressure of 29.921 in. Hg
t = dry-bulb temperature of moist air, °F
t_d = dew-point temperature of moist air, °F
t^* = thermodynamic wet-bulb temperature of moist air, °F
T = absolute temperature, °R
v = volume of moist air, per unit mass of dry air
v_a = specific volume of dry air
$v_{as} = v_s - v_a$
v_f = specific volume of saturated liquid water
$v_{fg} = v_g - v_f$
v_g = specific volume of saturated water vapor
v_s = volume of moist air at saturation, per unit mass of dry air
v_T = total gas volume
V = total volume of moist air sample
W = humidity ratio of moist air, mass of water per unit mass of dry air
W_s = humidity ratio of moist air at saturation
W_s^* = humidity ratio of moist air at saturation at thermodynamic wet-bulb temperature
x_a = mole-fraction of dry air, moles of dry air per mole of mixture
x_w = mole-fraction of water, moles per mole of mixture
x_{ws} = mole-fraction of water vapor under saturated conditions, moles of vapor per mole of saturated mixture

CHAPTER 7

SOUND AND VIBRATION

Acoustical Design 7.1
Characteristics of Sound 7.1
Basic Definitions 7.2
Human Response to Sound 7.3
Measuring Sound and Vibration 7.4
Determining Sound Power 7.5
Converting from Sound Power to Sound Pressure 7.6
Typical Sources of Sound 7.6
Sound Transmission Paths 7.7
Noise Control 7.7
Acoustical Design Goals and Rating Systems 7.8
Fundamentals of Vibration 7.11

THE design, installation, and use of HVAC and refrigeration systems, without attention to sound and vibration control, can result in complaints due to an unacceptable acoustical environment. These problems can be avoided if fundamental principles of sound and vibration control are applied. This chapter introduces these principles, including characteristics of sound; basic definitions and terminology; human response to sound; acoustical design goals; the source/path/receiver concept in sound and vibration control; and vibration isolation fundamentals. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* and the references listed at the end of this chapter provide further information on the subject.

ACOUSTICAL DESIGN

The primary objective of HVAC system and equipment acoustical design is to create an appropriate acoustical environment for a given space. To achieve appropriate sound levels, the source/path/receiver concept must be applied; *i.e.*, sound and vibration are created by a *source*, transmitted along one or more *paths*, and reach a *receiver*. Treatments and modifications can be applied to any or all of these elements to achieve a proper acoustical or vibration environment.

CHARACTERISTICS OF SOUND

Sound is a travelling oscillation in a medium exhibiting the properties of both elasticity and inertia. In fluid media (air or water), the disturbance travels as a longitudinal wave. Sound is generated by a vibrating surface or a turbulent fluid stream. In HVAC system design, both air- and structureborne sound propagation are of concern.

Speed

The speed of a longitudinal wave in a fluid medium is a function of the medium's density and modulus of elasticity. In air, at room temperature, the speed of sound is about 1100 ft/s; in water, about 5000 ft/s.

Frequency

Frequency is the number of oscillations (or cycles) per second completed by a vibrating object. The international unit for frequency is hertz (Hz).

Wavelength

Wavelength is the distance between successive rarefactions or compressions of the propagation medium. Wavelength, speed, and frequency are interrelated by the following equation:

$$\lambda = c/f \quad (1)$$

where

λ = wavelength, ft
c = speed of sound, ft/s
f = frequency, Hz

Frequency Spectrum and Bandwidths

The audible frequency range extends from about 20 Hz to 20 kHz. In some cases, infrasound (< 20 Hz) or ultrasound (> 20 kHz) are important, but methods and instrumentation for these frequency regions are specialized and are not considered here. Within the frequency range of interest, a sound source is characterized by its sound power output in octave or 1/3 octave bands, although narrower bandwidths may be appropriate for certain analyses. An octave is a frequency band with its upper band limit twice the frequency of its lower band limit. Table 1 lists the preferred series of octave bands and the upper and lower band limit

Table 1 Center Approximate Cutoff Frequencies for Octave and 1/3 Octave Band Series (ANSI *Standard* S1.6)

The preparation of this chapter is assigned to TC 2.6, Sound and Vibration Control.

frequencies. An octave band can, on a logarithmic frequency scale, be divided into three equally wide 1/3 octave bands with upper and lower frequency limits in the ratio of the cube root of two to one. One-third octave band center frequencies and upper and lower band limits are also listed in Table 1. The center frequency of an octave or 1/3 octave band is the geometric mean of its upper and lower band limits. Octave and 1/3 octave bands are identified by their center frequencies, not by their upper and lower band limit frequencies (ANSI *Standard* S1.11). While analysis in octave bands is usually acceptable for rating acoustical environments in rooms, 1/3 octave band analysis is often useful in product development and troubleshooting investigations.

Noise

The first and simplest definition of noise is any unwanted sound. The second definition is that noise is broadband sound with no distinguishable frequency characteristics, such as the sound of a waterfall. This definition is appropriate when one sound is used to mask another, as when controlled sound radiated into a room from a well-designed air-conditioning system is used to mask or hide low-level intrusive sounds from adjacent spaces to increase privacy. This controlled sound is called noise, but not in the context of unwanted sound; rather, it is a broadband, bland sound that is frequently unobtrusive. Three types of noise in the second context are frequently encountered in acoustics:

1. Random noise is an oscillation, the instantaneous magnitude of which is not specified for any given instant. The instantaneous magnitudes of a random noise are specified only by probability distributions, giving the fraction of the total time that the magnitude, or some sequence of magnitudes, lies within a specified range.
2. White noise has a continuous frequency spectrum with equal energy/Hz over a specified frequency range. In this sense, it is like white light. White noise is not necessarily random.
3. Pink noise also has a continuous frequency spectrum, but has equal energy per constant-percentage bandwidth, such as per octave or 1/3 octave band. The need for pink noise arose primarily in acoustical laboratory testing. Since the octave bands in white noise double in width for each successive band, the energy in the band also doubles in each successive band. Pink noise, a constant energy per bandwidth noise, is obtained by sloping the energy profile by 3 dB per octave.

BASIC DEFINITIONS

Decibel

The decibel (dB) is a basic unit of measurement in acoustics. Its use is often confusing because it is used to quantify many different descriptors relating to sound source strength, sound level, and sound attenuation. For this reason, it is important to be aware of the context in which the term is used.

Numerically, the decibel is ten times the base 10 logarithm of the ratio of two like quantities proportional to acoustical power or energy. The term level, when used in relation to sound power, sound intensity, or sound pressure, connotes that dB notation is being used. A reference quantity is always implied if it does not appear.

Sound Intensity and Sound Intensity Level

If a sphere is circumscribed around an arbitrary distance from a source, all the energy radiated by the source must pass through the sphere. Power flow through a unit area of the sphere is intensity, expressed in watts per square meter. (The SI system units are used here rather than I-P system units because of international agreement on the definition.) Sound intensity follows the inverse square law; *i.e.*, sound intensity varies inversely as the square of distance from the source. This is true for acoustical sources outdoors and, to a limited extent, indoors. Sound intensity level is expressed in dB with a reference quantity of 10^{-12} W/m^2.

Sound Pressure and Sound Pressure Level

Sound intensity is difficult to measure directly. On the other hand, sound pressure is relatively easy to measure; the human ear and microphones are pressure-sensitive devices. It can be shown that pressure squared is proportional to intensity. Using the same techniques, a decibel scale for sound pressure can be created in a manner analogous to the decibel scale for sound intensity. In this case, the reference pressure is 20 μPa, which corresponds to the approximate threshold of hearing. Since pressure squared is proportional to intensity, sound pressure level is:

$$L_p = 10 \log (p/p_{ref})^2 \text{ re } p_{ref} \quad (2)$$

Since p_{ref} is 20 μPa, which is 2×10^{-5} Pa, and since $10 \log p^2 = 20 \log p$:

$$L_p = 20 \log (p/2 \times 10^{-5}) \text{ re } 20\ \mu\text{Pa} \quad (3)$$

where p is the root mean square (rms) value of pressure in micropascals. Or

$$L_p = 20 \log p + 94 \text{ dB re } 20\ \mu\text{Pa} \quad (4)$$

The human ear responds across a broad range of sound pressures; threshold of hearing to threshold of pain covers a range of approximately 10^{14}:1. The linear range scale for sound pressure in Table 2 is awkward in this form; therefore, the equivalent logarithmic notations in the third column of Table 2 should be used. Table 2 also gives the sound pressures and sound pressure levels of various typical sources.

Since the decibel is a logarithmic unit, two sound levels cannot be added arithmetically. Two common methods for adding decibels are used. For the more accurate method of adding sound pressure levels, divide each by 10 and take the antilogarithm. Then

Table 2 Typical Sound Pressures and Sound Pressure Levels

Source	Sound Pressure, Pa	Sound Pressure Level, dB re 20μPa	Subjective Reaction
Military jet takeoff at 100 ft	200	140	Extreme danger

Table 3 Combining Decibels to Determine Overall Sound Pressure Level

Octave Band Frequency, Hz	Octave Band Level, L_p	Antilog	
63	85	$3.2 \times 10^8 = 0.32$	$\times 10^9$
125	90	$1.0 \times 10^9 = 1.0$	$\times 10^9$
250	92	$1.6 \times 10^9 = 1.6$	$\times 10^9$
500	87	$5.0 \times 10^8 = 0.5$	$\times 10^9$
1000	82	$1.6 \times 10^8 = 0.16$	$\times 10^9$
2000	78	$6.3 \times 10^7 = 0.06$	$\times 10^9$
4000	65	$3.2 \times 10^6 = 0.003$	$\times 10^9$
8000	54	$2.5 \times 10^5 = 0.0002$	$\times 10^9$
		3.6432×10^9	

$10 \log (3.6 \times 10^9) = 96$ dB

add the antilogarithms—take the logarithm, and multiply by 10 to obtain the combined level. The process can be used to add a series of decibel levels, such as the octave band analysis of a noise (Table 3), to reach the overall level. As previously noted, this can be done by converting all the levels to mixed notations, adding them, and converting back to logarithmic notations. Alternatively, add the largest and next largest, and repeat this process until the next addition has little or no influence.

The second method is simpler and slightly less accurate. In this method, simply refer to Table 4 to perform the desired addition. This method, although not exact, results in errors of 1 dB or less.

Number of decibels to be added to higher level to obtain combined level	3	2	1	0

Sound Power and Sound Power Level

Referring back to the definition for sound intensity, note the provision for a sound source. A fundamental characteristic of an acoustic source is its ability to radiate energy, whether weak and small in size (a cricket) or strong and large (a compressor). Some energy input excites the source, which radiates some fraction of this energy in the form of sound. Since unit power radiated through a unit sphere yields unit intensity, the power reference base, established by international agreement, is 1 picowatt (pW) (10^{-12} W). The reference quantity used should be stated explicitly. A definition of sound power level is, therefore:

$$L_w = \log (w/10^{-12}\text{W}) \text{ dB re 1 pW}$$

or

$$L_w = 10 \log w + 120 \text{ dB re 1 pW} \quad (5)$$

Sound power outputs for common sources are shown in Table 5.

Table 5 Typical Sound Power Outputs and Sound Power Levels

Source	Approximate Power Output, Watts	Approximate Power Output, Decibel re: 10^{-12} W

HUMAN RESPONSE TO SOUND

Objective Determination

Objectively determining the subjective reaction to sound in terms of loudness is complex; the primary method for determining this reaction is a statistically representative sample of human observers. To determine the loudness of a sound, a standard sound is chosen; a sampling of people compares an unknown sound with the standard sound. The accepted standard sound is a pure tone of 1000 Hz or a narrow band of random noise centered on 1000 Hz. The loudness level of sound is defined as the sound pressure level of a standard sound that seems to be as loud as the unknown to the sample observers. Loudness level is expressed in phons, and the loudness level of any sound in phons is equal to the sound pressure level in decibels of an equally loud standard sound. Therefore, a sound that is judged to be as loud as a 40-dB, 1000-Hz tone has a loudness level of 40 phons. Statistical reactions of humans to pure tones are shown in Figure 1 (Robinson and Dadson 1956). The reaction changes when the sound is a band of random noise (Pollack 1952), rather than a pure tone (Figure 2). These curves are equal loudness contours and were developed by asking the subjects to match the loudness of tones or bands of random noise presented at other frequencies and levels to the loudness of a tone or band centered on 1000 Hz. The figures indicate that the human perception of sound is most sensitive in the mid-frequency range.

The designer's fundamental concern is how humans respond to sound; frequently this is only generally related to the variation of sound energy. Humans subjectively say that one sound is louder than another, higher or lower pitched, etc. Under carefully controlled experimental conditions, humans can detect small changes in sound level. However, the human reaction describing the halving or doubling of loudness requires changes in a sound pressure level of about 10 dB. For broadband sounds, 3 dB is the minimum perceptible change. This means that halving the power output of

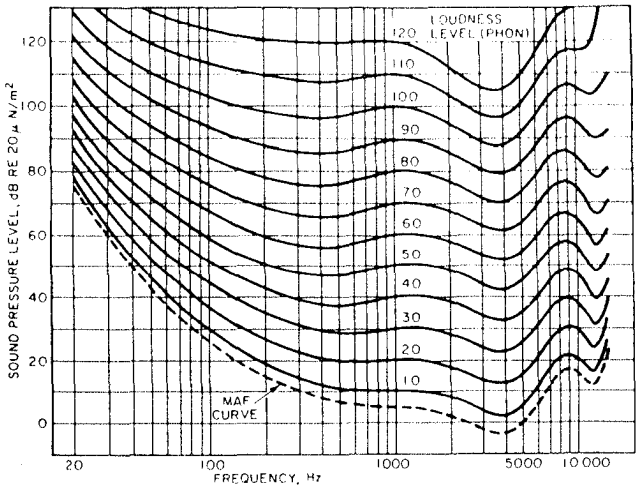

Fig. 1 Free-Field Loudness Contours for Pure Tones

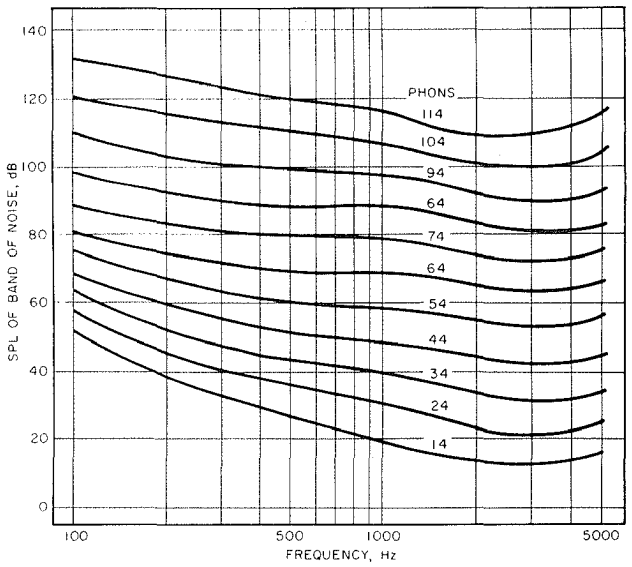

Fig. 2 Equal Loudness Contours for Relatively Narrow Bands of Random Noise

Table 6 Subjective Effect of Changes in Sound Pressure Level, Broadband Sounds

Change in Sound Pressure Level	Apparent Change in Loudness
3 dB	Just noticeable
5 dB	Clearly noticeable
10 dB	Twice (or half) as loud

the source causes a barely noticeable change in sound pressure level, and the sound power output must be reduced by a factor of 10 before humans determine that loudness has been halved. Subjective changes are shown in Table 6.

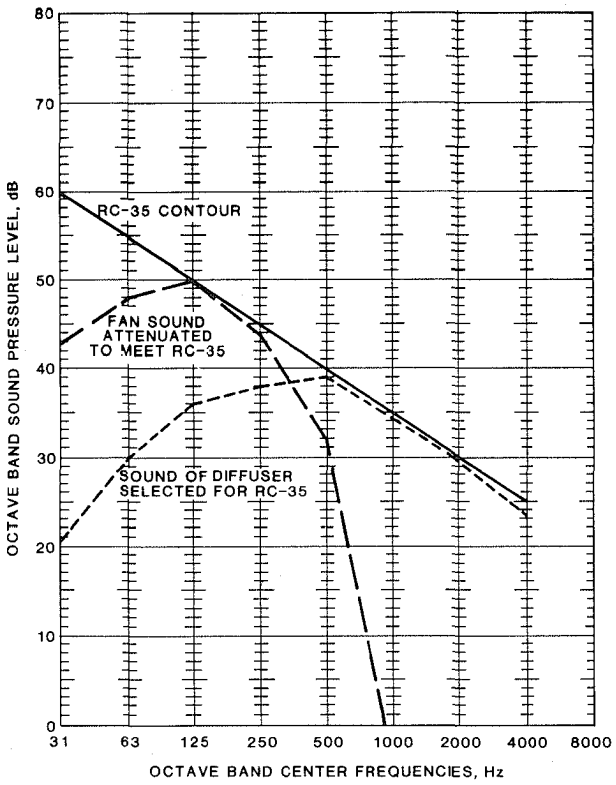
Quality of Sound

The way in which humans react to the quality of sound is as important to the designer as their reaction to the loudness. Sound quality is a function of the relative intensities of sound levels in each region of the audible frequency spectrum and the presence of tones or level fluctuations. Figure 3 shows an indoor sound spectrum and the manner in which fan and diffuser noise contributes to that spectrum at various frequencies. The fan noise has been attenuated to a degree that it approaches the sound criterion (in this case an RC-35 contour) only in the lower octave bands. If this were the only noise present in the space, it would be considered rumbly by most listeners. However, the diffusers have been selected to balance the spectrum by filling in the higher frequencies so that the quality of the sound is more pleasant. Unfortunately, achieving a balanced sound spectrum is not usually this easy—there may be a multiplicity of sound sources to consider. As a guide to the designer, Figure 4 shows the more common mechanical and electrical noise sources and frequency regions that control the indoor noise spectrum. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* provides more detailed information on treating some of these noise sources.

MEASURING SOUND AND VIBRATION

Instrumentation

The great majority of HVAC sound level measurements can be made using a battery-operated, handheld sound level meter with an attached filter set. The meter uses a microphone, internal



OCTAVE BAND SOUND PRESSURE LEVEL, dB

Fig. 3 Well-Balanced Sound Spectrum Resulting from Proper Selection of Air Outlets and Adequate Fan Noise Attenuation

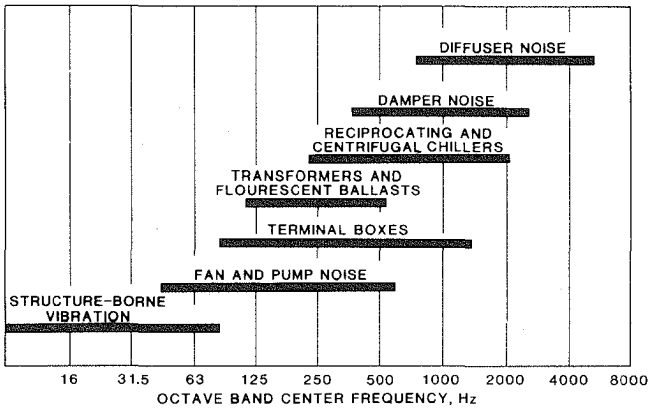

Fig. 4 Frequencies at which Various Types of Mechanical and Electrical Equipment Generally Control Sound Spectra

electronic circuits, and a readout display to measure and display the L_p at the desired location. The most useful meters have high (Type 1) or moderate (Type 2) precision; Linear, A, and C weighting networks; octave band filters with center frequencies from 31 to 8000 Hz; and a moving needle or LCD thermometer-style display to show sound level fluctuations. Some manufacturers also provide 1/3 octave band filters for their handheld meters. Sound level meters without octave or 1/3 octave band filters are much less valuable because, in a troubleshooting situation, they provide only limited help in determining the frequency content of the offending noise, a necessary step in determining noise reduction strategies.

Measurement Procedures

Determining the sound spectrum in a room or troubleshooting a noise complaint usually requires measuring the octave band

Table 7 Guidelines for Determining Equipment Sound Levels in Presence of Contaminating Background Noise

Measurement A minus Measurement B	Correction to Measurement A to Obtain Equipment Sound Level
10 dB or more	0 dB
6 to 9 dB	−1 dB
4 to 5 dB	−2 dB
3 dB	−3 dB
2 dB	−4 dB
1 dB	−7 dB
0 dB	Equipment sound level is at least 9 dB below Measurement A

Measurement A = Tested equipment plus background noise
Measurement B = Background noise alone

L_p values in the octave bands from 31 to 4000 Hz. In cases where tonal noise or rumble is the complaint, 1/3 octave band measurements are recommended because of their ability to discriminate narrower frequency bands of noise.

Measuring noise emissions from a particular piece of equipment or group of equipment requires a measurement plan specific to the situation. The Air-Conditioning and Refrigeration Institute (ARI), the Air Movement and Control Association (AMCA), the American Society of Testing and Materials (ASTM), the American National Standards Institute (ANSI), the Acoustical Society of America (ASA), and ASHRAE all publish sound level measurement procedures for various laboratory and field noise measurement situations.

Sometimes the noise due to a particular piece of HVAC equipment must be measured in the presence of background noise from other sources that cannot be turned off, such as automobile traffic or certain business machines. Determining the sound level due to the selected equipment alone requires making two sets of measurements, one set with the HVAC equipment operating with the background noise and another set with only the background noise (with the equipment turned off). This situation might occur, for example, when determining whether or not the property line noise exposure from a cooling tower meets a local noise ordinance. The guidelines given in Table 7 will help to determine the sound level of a particular machine in the presence of background noise.

Vibration Measurements

While the control of HVAC system noise and vibration are of equal importance, the measurement of vibration is not usually necessary for determining the sources or transmission paths of disturbing noise. In addition, the techniques and instrumentation used for vibration measurement and analysis are specialized and beyond the scope of this handbook. Therefore, designers should consult other sources (*e.g.*, Harris 1991) for descriptions of vibration measurement and analysis methods.

DETERMINING SOUND POWER

Sound power cannot be determined directly. Rather, it is determined by measuring the sound pressure or sound intensity created by a source under one of several circumstances and then calculating the sound power. Sound power is determined by measuring one of four different quantities—sound pressure in a free field, sound pressure in a reverberant field, sound pressure in a progressive wave field, or sound intensity in a nonreactive field.

Free-Field Method

A sound field in which the effects of the boundaries are negligible over the frequency range of interest is a free field. In a free field or in spaces where free-field conditions can be approximated (*e.g.*, by sound-absorbing walls, floor, and ceiling), the sound power of a sound source can be determined from a number of sound pressure level measurements around the source and equally spaced from it. This method is based on the fact that, since absorption of sound in air can be practically neglected at small distances from the sound source, the sound power generated by a source must flow through an imagined sphere with the source at its center. The intensity of the sound is determined at each of the measuring points around the source and multiplied by the area of the imagined sphere associated with the measuring points. Total sound power is the sum of these products for each point.

Using numerical values of acoustic velocity c for air at 68 °F and 14.7 psi (standard atmosphere) and using sound power level L_w (dB re 10^{-12} W) and sound pressure level L_p (dB re 20 μPa), yields the following relationships between sound power level and sound pressure level for a nondirectional sound source, measured in a free field at a distance r (in feet):

$$L_w = L_p + 20 \log r + 0.5 \text{ dB} \quad (6)$$

Actual sound sources radiate different amounts of sound power in different directions, because the source is a certain size and the various areas of its surface do not necessarily vibrate at the same level or in phase. A directivity pattern can be established by measuring sound pressure under free-field conditions, either in an anechoic room or over a reflecting plane. Directivity is described by the directivity factor Q, which is a function of frequency and direction. Directivity is defined as the ratio of sound pressure at a given angle from the sound source to the sound pressure that would be produced by the same source radiating uniformly in all directions. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* provides more detailed information on sound source directivity.

Since most sound sources have more or less pronounced directional characteristics, measurements have to be made at several points. ANSI *Standard* S12.35 describes various methods used to calculate the sound power level under free-field conditions.

In many cases, a fully free field is not available, and measurements have to be made in a free field over a reflecting plane. This means that the sound source is placed on a hard floor (in an otherwise sound-absorbing room) or on pavement outdoors. Since the sound is then radiated into a hemisphere rather than a full sphere, the relationship for L_w and L_p for a nondirectional sound source is:

$$L_w = L_p + 20 \log r - 2.5 \text{ dB} \quad (7)$$

The free-field method, with measurements made in a room with sound-absorbing walls, floor, and ceiling, is limited in the lower frequencies by the difficulty of obtaining room surface treatments that have high sound absorption coefficients at low frequencies. For example, a glass fiber wedge structure useful at 70 Hz must be at least 4 ft long.

Reverberant Field Method

A sound field in which the sound intensity is the same in all directions and at every point due to reflections from the room surfaces is called a reverberant field. Another widely used method to determine sound power places the sound source in a reverberation room that has sound-reflecting walls, floor, and ceiling. The sound pressure level is then measured at some distance from the source and the surfaces of the room. The sound power level is calculated from the sound pressure level, if the rate of decay of sound (in dB/s) and the volume of the reverberation room are known (direct method). Alternately, the sound pressure level of a reference sound source (RSS) with known sound power output in the reverberation room may be measured, and then the un-

known sound source may be measured to obtain its sound power output through comparison (substitution method).

Standardized methods for determining the sound power of HVAC equipment in reverberation rooms are given in ANSI *Standard* 12.31-90, when the sound source contains mostly broadband noise; ANSI *Standard* 12.32-90, when tonal noise is prominent; and AMCA *Standard* 300-85 for testing fans.

The relationship between sound power level and sound pressure level in a reverberation room is given by:

$$L_w = L_p + 10 \log V + 10 \log D - 47.3 \text{ dB} \quad \text{(direct method)} \quad (8)$$

and

$$L_w = L_p + (L_w - L_p)_{ref} \quad \text{(substitution method)} \quad (9)$$

where

L_p = sound pressure level averaged over room
V = volume of room, ft^3
D = decay rate, dB/s
$(L_w - L_p)_{ref}$ = difference between sound power level and sound pressure level of reference sound source

Some sound sources that can be measured by these methods are room air conditioners, refrigeration compressors, components of central HVAC systems, and air terminal devices. AMCA *Standard* 300-85 and ARI *Standard* 880-89 establish special measuring procedures for some of these units. Large equipment that can operate on a large paved area, such as a parking lot, can also be measured under free-field conditions on a reflecting plane. Determining the sound power of large equipment is difficult; however, data may be available from some manufacturers.

Progressive Wave Method

One form of sound propagation is the progressive movement of a sound wave along a duct. Fan sound power can be determined in a progressive wave field by measuring the sound pressure level inside a duct. The method is described in detail in ASHRAE *Standard* 68-1986 (AMCA *Standard* 330-86) for in-duct testing of fans.

Sound Intensity Method

Recent advances in acoustical instrumentation now permit the direct determination of sound intensity, previously defined as the sound power per unit area flowing through a control surface. By measuring the sound intensity over the sphere or hemisphere surrounding a sound source, the spatially averaged sound power radiated by the source can be determined. One of the advantages of this method is that, with a few limitations, sound intensity (and, therefore, sound power) measurements can be made in the presence of background noise in ordinary rooms, thereby eliminating the need for a special testing environment. Another advantage is that by measuring sound intensity over restricted areas around a sound source, sound directivity can be determined. This procedure can be particularly useful in reducing noise of products during their development.

Sound intensity measurement procedures are still experimental and as yet no national or international standards exist. One particular concern is that small test rooms or those having somewhat flexible boundaries (sheet metal or thin drywall) can permit a reactive sound field to exist, one in which the room's acoustical characteristics cause it to affect the sound power output of the source.

Measurement Bandwidths

Sound power is normally determined in octave or 1/3 octave bands. Occasionally, a more exact determination of the sound source spectrum is required. In these cases, narrowband analysis, using either constant relative bandwidth (*e.g.*, 1/12 octave) or constant absolute bandwidth (*e.g.*, 5 Hz) can be applied. The most frequently used analyzer types are digital filter analyzers for constant relative bandwidth measurements and fast Fourier transform (FFT) analyzers for constant bandwidth measurements. Narrowband analysis results are used to determine the exact frequencies of pure tones and their harmonics in a sound spectrum.

CONVERTING FROM SOUND POWER TO SOUND PRESSURE

Provided with sound power level information on a source, the designer may be required to convert the sound power level to predict the sound pressure level at a given location.

The sound pressure level at a given location in a room relative to a source of known sound power level depends on: (1) room volume, (2) room furnishings and surface treatments, (3) magnitude of the sound source(s), and (4) distance from the sound source(s) to the point of observation.

In most typical rooms, the presence of acoustically absorbent surfaces and sound-scattering elements, such as furniture, creates a relationship between sound power and sound pressure level that is independent of the absorptive properties of the space. For example, hospital rooms, which have only a small amount of absorption, and executive offices, which have substantial absorption, are similar when the comparison is based on the same room volume and distance between the source and point of observation.

Equation (10) can be used to estimate the sound pressure level at a chosen observation point in a normally furnished room. The estimate is accurate to ±2 dB (Schultz 1985).

$$L_p = L_w - 5 \log V - 3 \log f - 10 \log r + 25 \text{ dB} \quad (10)$$

where

L_p = room sound pressure level at chosen reference point, dB re 20 μPa
L_w = source sound power level, dB re 10^{-12} W
V = room volume, ft^3
f = octave band center frequency, Hz
r = distance from source to observation point, ft

Equation (10) applies to a single sound source in the room. With more than one source, total sound pressure level at the observation point is obtained by adding (on an energy basis) the individual contribution of each source, using the corresponding L_w and r for each source.

TYPICAL SOURCES OF SOUND

Whenever mechanical power is generated or transmitted, a fraction of this power is converted into sound power and radiated into the air. Sound source characteristics depend on the form of mechanical power and the type of medium or structure of the mechanical power generation or transmission system. The most important sound source characteristics include total sound power output L_w, frequency spectrum, and radiation directivity Q.

Sound sources are so numerous that it is impossible to provide a complete listing. All mechanical and most electrical equipment is capable of generating noise and vibration. Typical sources of noise and vibration in building mechanical systems are:

- Rotating and reciprocating equipment such as fans, motors, pumps, and chillers. A minor unbalance in this equipment can vibrate machine surfaces to produce airborne noise.
- Air and fluid noises such as those associated with ductwork, piping systems, grilles, diffusers, terminal boxes, manifolds, and pressure-reducing stations.

- Excitation of surfaces, for example, friction; movement of mechanical linkages, ducts, and pipes; and impact within mechanisms, such as cams and valve slap.
- Magnetostriction (transformer hum), which becomes significant in motor laminations, transformers, switchgear, lighting ballasts, and dimmers. A characteristic of magnetostrictive oscillations is that their fundamental frequency is twice the line frequency (120 Hz in a 60 Hz system).

SOUND TRANSMISSION PATHS

Sound from a source is transmitted via a path to a receiver. Airborne and structureborne transmission paths are of principal concern for the HVAC system designer. Airborne paths can be via the atmosphere or through ductwork; structureborne paths are via solid materials. Room-to-room paths comprise both airborne and structureborne transmission paths. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* has additional information on transmission paths.

Airborne Transmission

Atmospheric transmission. Sound transmits readily in the atmosphere, both indoors and outdoors. Indoor sound transmission differs from outdoor transmission due to the presence of room boundaries, which allow sound reflections. Thus, in most rooms, sound can be transmitted via a straight-line direct path from the source to the receiver, by one or more reflected paths (from the source to the receiver via boundary reflections), or by a combination of both. Sound propagation indoors does not follow the inverse square law. Outdoors, the effects of the reflections are small, provided that the source is not located near large reflecting surfaces. However, sound outdoors can refract and change propagation direction due to the presence of wind and temperature gradient effects. Sound propagation outdoors follows the inverse square law. Therefore, Equations (6) and (7) can be used to calculate the relationship between sound power level and sound pressure level for fully free-field and hemispherical free-field conditions, respectively.

Ductborne transmission. Ductwork can provide an effective sound transmission path since the sound is readily contained within the boundaries of the ductwork. Sound can transmit both upstream and downstream from the source. A special case of ductborne transmission is crosstalk, where sound is transmitted from one room to another via the duct path.

Room-to-room transmission. Room-to-room sound transmission generally involves both airborne and structureborne sound paths. The sound power incident on a room surface element undergoes three transmission phenomena: (1) some of the sound energy is reflected from the surface element back into the room, (2) a portion of the sound energy is lost as energy transfer to the material comprising the element, and (3) the remainder of the sound energy is transmitted through the element to the other room. Airborne sound is radiated as the element vibrates, and structureborne sound can be transmitted via interconnecting studs or the floor. Some of the sound from the source room can be radiated around the primary separating element and into the receiving room via sound flanking. A common sound flanking path is the return air plenum.

Structureborne Transmission

Solid structures are efficient transmission paths for sound, which frequently originates as a vibration imposed on the transmitting structure. The vibration can be either a single impulse or a steady-state energy input. Typically, only a small amount of the input energy is radiated by the structure as airborne sound. A lightweight structure with little inherent damping radiates more sound than a massive structure with greater damping.

NOISE CONTROL

Terminology

The following noninterchangeable terms are used to describe the acoustical performance of many system components. ASTM *Standard* C634 defines additional terms used to describe acoustical performance parameters.

Sound attenuation is a general term describing the reduction of the intensity of sound as it travels from a source to a receiver.

Insertion loss (IL) of a silencer or other sound-reducing element is expressed in dB and is defined as the decrease in sound pressure level or sound intensity level, measured at the location of the receiver, when the silencer or a sound-reducing element is inserted into the transmission path between the source and the receiver. For example, a duct silencer would be replaced by a section of straight unlined duct to determine the silencer's insertion loss. Measurements are typically made in octave bands.

Sound transmission loss (TL) of a partition or other building element is expressed in dB and is the loss equal to 10 times the common logarithm (base 10) of the ratio of the airborne sound power incident on the partition to the sound power transmitted by the partition and radiated on the other side. Measurements are typically made in octave or 1/3 octave bands. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* defines the special case of breakout transmission loss through duct walls.

Noise reduction (NR) is also expressed in dB and is the difference between the space-time average sound pressure levels produced in two enclosed spaces or rooms by one or more sound sources in the rooms. An alternate, non-ASTM definition of NR is the difference in sound pressure levels measured upstream and downstream of the silencer or sound-reducing element. Measurements are typically made in octave or 1/3 octave bands.

Sound absorption coefficient (α) is the fraction of the incident sound energy that is absorbed by a construction material or assembly. It is measured using 1/3 octave bands of broadband noise and is commonly reported at the full octave band center frequencies. The α value of a material in a specific octave band depends on the material's thickness, flow resistivity, stiffness, and method of attachment to the supporting structure. Duct and plenum liners are usually fibrous materials with high sound absorption values at mid to high frequencies.

Spherical spreading is the decrease in sound intensity due to the effects of inverse square law propagation. It occurs when the sound source is located either in free space or positioned on a reflecting plane.

Scattering is the change in direction of sound propagation due to an obstacle or inhomogeneity in the transmission medium. It results in the incident sound energy being dispersed in many directions.

Enclosures and Barriers

Enclosing the noise source is a common means of controlling airborne sound transmission. A homogeneous, single panel has a certain weight or mass per unit area and a certain stiffness and internal resistance; the sound transmission loss of such a panel has a frequency characteristic like the one shown in Figure 5. For most common materials, audible frequencies are in the mass-controlled part of the curve. The transmission loss (TL) of a limp panel without stiffness, with sound impinging perpendicular to the panel, is modeled by the mass law equation for sound at normal incidence, giving:

$$TL_o = 20 \log w_s f - 28 \text{ dB} \quad (11)$$

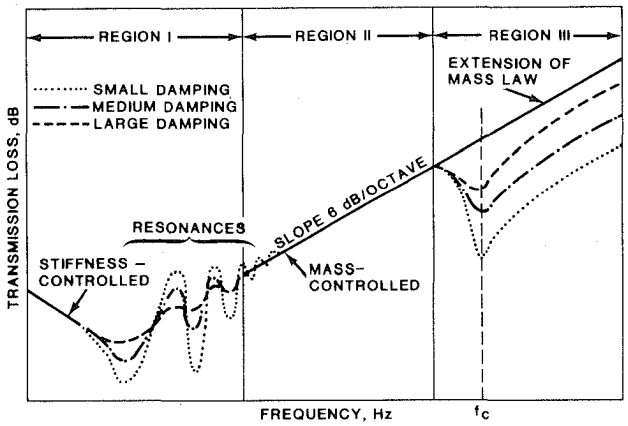

Fig. 5 Typical Transmission Loss of Panel

where w_s is the surface mass of the panel in lb/ft^2 and f is the frequency in Hz. For homogeneous panels, heavy materials attenuate sound better than light materials. Transmission loss in a diffuse sound field is averaged over all angles of incidence to yield:

$$TL_{random} = TL_o - 10 \log (0.23\ TL_o)\ \text{dB} \qquad (12)$$

Thus, the random incidence transmission loss of common building materials is often 5 to 10 dB less than the normal incidence transmission loss.

If the sound fields on both sides of a panel are diffuse, the panel's noise reduction is a function of its area S_p and the total sound absorption A_r in the receiving space, according to the following equation:

$$NR = TL + 10 \log A_r - 10 \log S_p\ \text{dB} \qquad (13)$$

Since the total sound absorption in a room is expressed as the equivalent area of perfect sound absorption, both S_p and A_r are expressed in consistent units, usually square feet.

The sound transmission class (STC) rating of a partition or assembly is often used in architecture to classify sound isolation performance. However, the STC rating should not be used as an indicator of an assembly's ability to contain equipment noise or any source rich in low frequencies. The reason is that the STC rating system was developed to deal effectively with speech frequency sound sources (250 to 4000 Hz). It is possible for a drywall partition to have a higher STC rating than a masonry wall, yet the masonry wall is likely to isolate most HVAC noise sources more effectively. Because of the limited frequency range and selective frequency discrimination of most single number rating systems, the designer should work with octave band sound transmission loss values rather than single number ratings.

In many applications, noise reduction of an enclosure is severely compromised by openings or leaks in the enclosure. Ducts that lead into or through a noisy space can carry sound to many areas of a building. Designers should consider this when designing duct, piping, and electrical systems.

Attenuation of Noise in Ducts and Plenums

Most ductwork, even a sheet metal duct without acoustical lining or silencers, attenuates sound. The natural attenuation of unlined ductwork is minimal, but can, for long duct runs, significantly reduce ductborne sound. Acoustic lining of ductwork can greatly attenuate the propagation of sound through ducts, particularly at mid to high frequencies. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* has a detailed discussion of lined and unlined ductwork attenuation.

When lined ductwork cannot reduce sound propagation adequately, commercially available sound attenuators (also known as sound traps or duct silencers) can be used. There are three types: dissipative, reactive, and active. The first two are commonly known as passive silencers.

Dissipative silencers contain thick, perforated sheet metal baffles that restrict the air passage width within the silencer housing. The baffles are filled with low-density mineral fiber insulation. This type of silencer is most effective in reducing mid- and high-frequency sound energy.

Reactive silencers are similar to dissipative silencers except that the baffles are not filled with fibrous materials. This silencer type is typically used in HVAC systems serving hospitals, laboratories, or other areas with strict air quality standards. The reactive silencer acts as a complex of resonators that absorb incident sound energy via the Helmhotz resonator concept. Since reactive silencers do not contain fibrous materials, they are not as effective as dissipative silencers. Therefore, for equal performance, a reactive silencer must be longer than a dissipative silencer.

The first active silencers for commercial HVAC systems are currently being installed. Controlled laboratory arrangements have shown that active silencers effectively reduce both broadband and tonal noise in the 31 through 250 Hz octave bands. Active silencer systems use microphones, loudspeakers, and appropriate electronics to reduce in-duct noise by generating inverse phase sound waves that destructively interfere with the incident sound energy. Since the system's microphones and loudspeakers are mounted flush with the duct wall, there is no obstruction to airflow and, therefore, a negligible pressure drop. However, since active silencers are not effective in the presence of excessively turbulent airflow, their use is limited to relatively long, straight duct sections with an air velocity less than about 1500 ft/min.

Silencers and duct liner materials are tested according to ASTM *Standard* E477, which defines acoustical and aerodynamic performance in terms of insertion loss, self-generated noise (or self-noise), and airflow pressure drop. Insertion loss performance is measured in the presence of both forward and reverse flow. Forward flow occurs when the air and sound move in the same direction, as in a supply air or fan discharge system; reverse flow occurs when the air and sound travel in opposite directions, as in the case of a return air or fan intake system. Self-noise can limit a silencer's effective insertion loss for air velocities in excess of about 2000 ft/min. Use extreme caution when reviewing manufacturer's performance data for silencers and duct liner materials to be sure that the test conditions are representative of the specific design conditions.

End reflection losses due to abrupt area changes in duct cross section are sometimes useful in controlling low frequencies. The end reflection effect can be maximized at the end of a duct run by designing the last few feet of duct with the characteristic dimension of less than 15 in.

Where space is available, a lined plenum can provide excellent attenuation across a broad frequency range. The combination of end reflection at the plenum's entrance and exit, a large distance between the entrance and exit, and sound-absorbing lining on the plenum walls can perform as effectively as a duct silencer, but with less pressure drop.

Chapter 42 of the 1991 ASHRAE *Handbook—Applications* has additional information on the control of noise.

ACOUSTICAL DESIGN GOALS AND RATING SYSTEMS

Establishing Design Goals

The primary acoustical design goal for air-conditioning systems is the achievement of a level of background sound that is unob-

trusive in quality and low enough in level that it does not interfere with the occupancy requirements of the space being served.

For example, large conference rooms, auditoriums, and recording studios can tolerate only a low level of background sound before interference problems develop. On the other hand, higher levels of background sound are acceptable and even desirable in certain situations, such as in open-plan offices or music practice rooms, where a certain amount of speech and activity masking is essential. Therefore, the system noise control goal is a variable that depends on the required use of the space.

The degree of occupancy satisfaction achieved with a given level of background sound is multidimensional. To be unobtrusive, the background sound should be steady in level, bland in character, and free of identifiable machinery noises. Background sound should have the following properties:

- A balanced distribution of sound energy over a broad frequency range.
- No audible tonal characteristics such as a whine, whistle, hum, or rumble.
- No noticeable time-varying levels from beats or other system-induced aerodynamic instability.

Four types of acoustical design criteria are used by the air-conditioning industry: A-weighted sound level (dB), loudness (sones), noise criteria (NC) curves, and room criteria (RC) curves. A more detailed discussion of acoustical design goals, as well as a table of recommended design goals, can be found in Chapter 42 of the 1991 ASHRAE *Handbook—Applications.*

A-Weighted Sound Level

The A-weighted sound level (L_A) is widely used to state design goals as a single number, but its usefulness is limited because it gives no information on spectrum content. The measuring method is simple, since the L_A can be obtained from a single reading on a handheld instrument. The standard sound level meter includes an electronic weighting network that deemphasizes the low-frequency portions of a noise spectrum, automatically compensating for the lower sensitivity of the human ear to low-frequency sounds. Figure 6 shows the weighting characteristic of the A-weighting and C-weighting networks.

The A-weighted sound level has the advantage of identifying the desirable level as a single-valued number that correlates well with human judgment of relative loudness. However, it has the disadvantage of not correlating well with human judgment of relative noisiness or the subjective quality of a sound.

The A-weighted level comparison is best used with noises that sound alike but differ in level. It should not be used to compare sounds with distinctly different spectral characteristics; *i.e.*, two sounds at the same sound level, but with different spectral content, may be judged differently by the listener for an acceptable background sound. One of these noises might be completely acceptable, while the other could be objectionable because its spectrum shape was rumbly, hissy, or tonal in character.

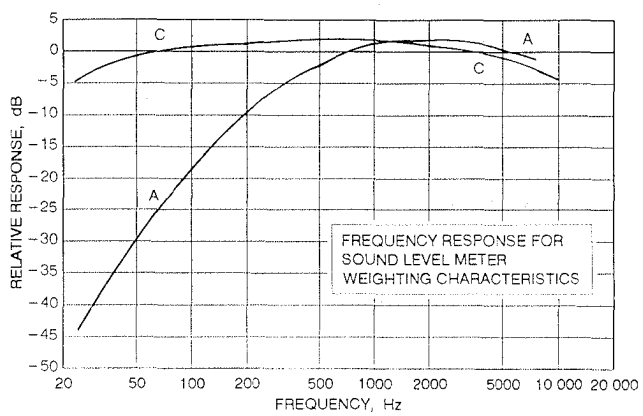

Fig. 6 Curves Showing A- and C-Weighting Responses

NC Curves

The noise criteria (NC) curves shown in Figure 7 (Beranek 1957) are widely used. These curves define the limits that the octave-band spectrum of a noise source must not exceed to achieve a level of occupant acceptance. For example, an NC-35 design goal is commonly used for private offices; the background noise level meets this goal, provided no portion of its spectrum lies above the designated NC-35 curve.

Two problems occur in using the NC design goal: (1) if the NC-level is determined by a singular tangent peak, the actual level of resulting background sound may be quieter than that desired for masking unwanted speech and activity noises because the spectrum on either side of the tangent peak drops off too rapidly, and (2) if the shape of the NC-curve is closely matched, the resulting sound will be either rumbly or hissy.

Because the shape of the NC-curve is not that of a well-balanced, bland-sounding noise, these curves should be used with caution in critical noise situations where the background sound of an air-conditioning system is required to mask speech and activity noise.

RC Curves

Room criteria (RC) curves (Figure 8) are designed especially for establishing HVAC system design goals. The shape of these curves differs from that of the NC curves at both low and high frequencies.

The shape of the RC curve is a close approximation to a well-balanced, bland-sounding spectrum. It provides guidance whenever the space requirements dictate that a certain level of background sound be maintained for masking or other purposes.

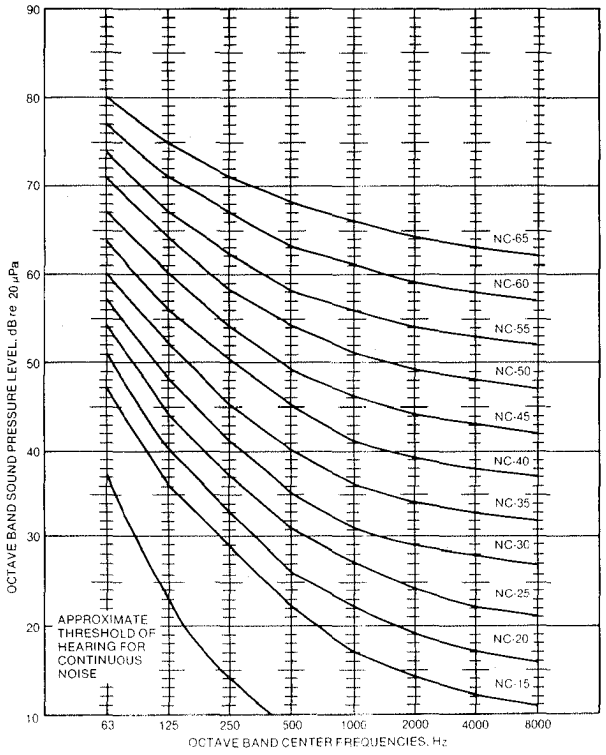

Fig. 7 NC Curves for Specifying Design Level in Terms of Maximum Permissible Sound Pressure Level for Each Frequency Band

Sound that approximates the shape of the curve within 2 dB over the entire frequency range achieves an optimum balance in quality. If the low-frequency levels (31.5 to 500 Hz) exceed the design curve by more than 5 dB, the sound is likely to be judged rumbly; exceeding the design curve by more than 3 dB at high frequencies (1000 to 4000 Hz) causes the sound to be judged hissy.

Another feature of the RC rating system is the presence of the shaded areas at high levels of low frequency noise. These regions predict conditions of frequency and level under which noise may induce lightweight constructions (gypsum walls or ceilings) and their attached services (electrical or HVAC system components) to vibrate or rattle.

Loudness (Sones) and Loudness Level (Phons)

Although the logarithmic phon scale covers the large dynamic range of the ear, it does not fit a subjective linear loudness scale. A sound that is twice as loud as another sound does not double the number of phons; as previously noted, over most of the audible range, a doubling of loudness corresponds to a change of approximately 10 phons. To obtain a quantity proportional to the loudness sensation, a loudness scale is defined in which the unit of loudness is known as a sone. One sone is equal to a loudness level of 40 phons.

ANSI *Standard* S3.4-80 calculates loudness or loudness level by using octave-band sound pressure level data as a starting point. These data are then plotted on a graph constructed as shown in Figure 9. After plotting this graph, the number corresponding to the loudness index for each octave band is obtained. Then total loudness is calculated:

$$S = S_m + 0.3\,(\Sigma S - S_m) \qquad (14)$$

where

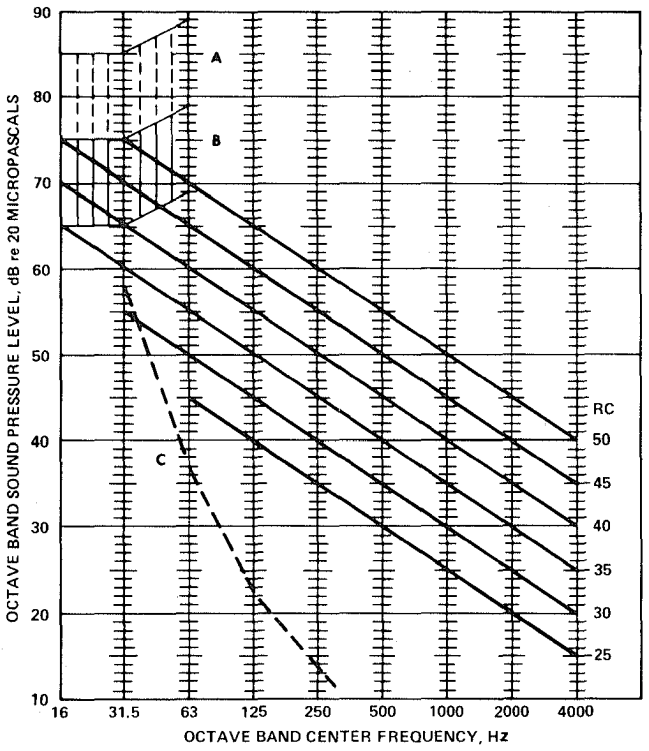
S = total loudness in sones
S_m = greatest loudness index
ΣS = sum of all loudness indices

After determining the loudness in sones, the loudness level in phons can be found on the right side of Figure 9. In interpreting loudness data, different authors have reported values based on differing loudness contours; also, several methods are available to calculate the single-number loudness or loudness level of a complex sound. For these reasons, this tool is not widely used in engineering practice because of its complexity and uncertainty. AMCA *Standard* 301 describes how the sone method is applied to rating the relative loudness of fans and ventilators.

This calculation method is usually acceptable when there are no strong tonal components in the measured sound spectrum. A more complex calculation method using 1/3 octave band sound pressure levels by Zwicker (ISO *Standard* 532) is more accurate in predicting loudness of sound spectra with tones.

A detailed discussion on the selection of sound design goals, as well as a table of recommended design goals, can be found in Chapter 42 of the 1991 ASHRAE *Handbook—Applications*. Sound levels below NC-35 or RC-35 contribute to good speech intelligibility, and those at or above NC-35 or RC-35 interfere with or mask speech. In mechanical systems with variable air volume, it may not be possible to fill in the higher frequencies when the quantity of supply air is moderate to low. In these cases, if acoustic privacy is important, it may be necessary to provide controlled amounts of electronic masking noise or to request the building designer to improve the sound-isolating construction.

Even if the occupancy noise is significantly higher than the ambient noise level, ambient noise levels should not necessarily be raised to levels approaching occupancy noise. Where speech contributes heavily to occupancy noise, raising the ambient noise levels raises the occupancy levels to the point of physical discomfort.



Region A: High probability that noise-induced vibration levels in lightweight wall and ceiling constructions will be felt; anticipate audible rattles in light fixtures, doors, windows, etc.
Region B: Noise-induced vibration levels in lightweight wall and ceiling constructions may be felt; slight possibility of rattles in light fixtures, doors, windows, etc.
Region C: Below threshold of hearing for continuous noise.

Fig. 8 RC Curves for Specifying Design Level in Terms of Balanced Spectrum Shape

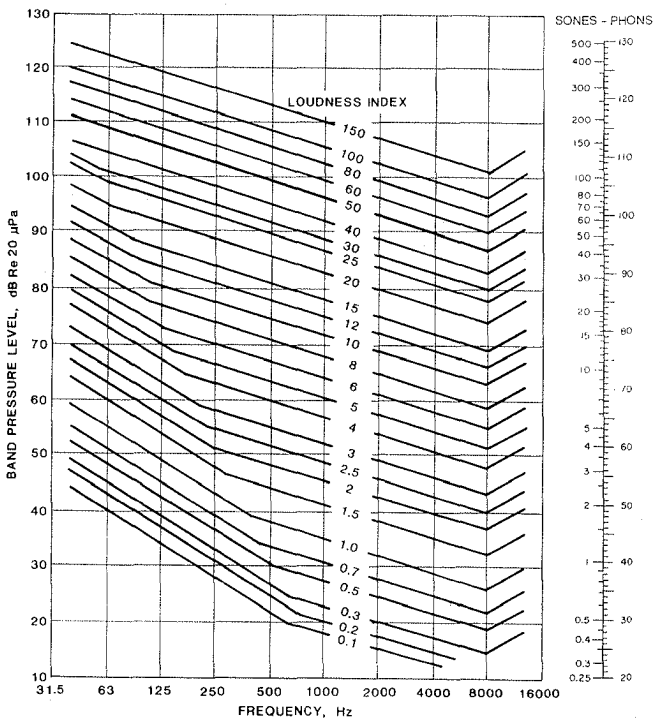


Fig. 9 Contours of Equal Loudness Index

FUNDAMENTALS OF VIBRATION

A rigidly mounted machine transmits all vibratory forces to its supporting structure. This vibration can be isolated or, more realistically, reduced to a fraction of the original force by inserting resilient mounts between the equipment and the building structure. The following sections on vibration isolation and information in Chapter 42 of the 1991 ASHRAE *Handbook—Applications* are useful in selecting vibration isolators and analyzing and correcting field vibration problems.

The following terms apply to vibration isolation:

M = mass of equipment, $lb_f \cdot s^2/in.$
M_f = mass of floor, lb
k = stiffness of isolator, $lb_f/in.$
k_f = stiffness of floor, $lb_f/in.$
F = vibratory force, lb_f
f = frequency of vibratory force (disturbing frequency), Hz
f_n = natural frequency of vibration isolation, Hz
f_f = natural frequency of floor, Hz
∂_{st} = static deflection of vibration isolator, in.
T = transmissibility, dimensionless ratio
$X''(\theta)$ = acceleration of system at time θ, in/s^2
X = displacement of equipment at time θ, in.
X_f = displacement of floor at time θ, in.

Vibration evaluation requires the study of system motion. Most applications can be treated as single- or two-degree of freedom systems where only motion along the vertical axis is considered, and damping is disregarded. Figure 10 schematically shows a single degree of freedom system where the equation of motion is:

$$M\ddot{X} + kX = F\sin(f_d)\theta \tag{15}$$

Displacement (absolute value) is given by:

$$X = \left|\frac{F/k}{1 - (f_d/f_n)^2}\right| \tag{16}$$

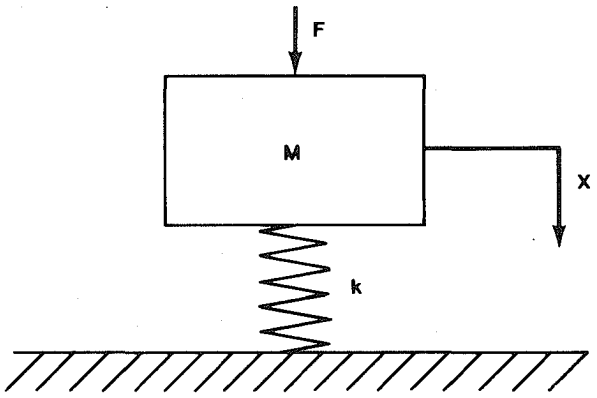

Fig. 10 Single Degree of Freedom System

where

$$f_n = \frac{1}{2\pi}\left(\frac{k}{M}\right)^{0.5}$$

and transmission (absolute value) to building structure is given by:

$$T = \left|\frac{1}{1 - (f_d/f_n)^2}\right| \tag{17}$$

The disturbing vibration can be caused by unbalance, misalignment, eccentricities in rotating components, or defective bearings; if the frequency of the disturbing vibration is not known, it can be considered to be the lowest rotating frequency. Transmissibility T is the ratio of force transmitted by the isolator (to the floor) to force applied by the equipment. For spring isolators commonly used with HVAC equipment, the natural frequency of the isolator f_n is a function of the isolator static deflection (the distance the spring compresses under the supported equipment), as shown in Figure 11.

Equation (17) indicates that the amount of transmitted energy is a function of disturbing frequency f_d to isolator natural frequency f_n, and varies as the square of this ratio. As shown in Figure 12, when $f_d = f_n$, the denominator of Equation (17) equals zero and theoretically infinite transmission exists—a condition known as resonance. In actual resonant conditions,

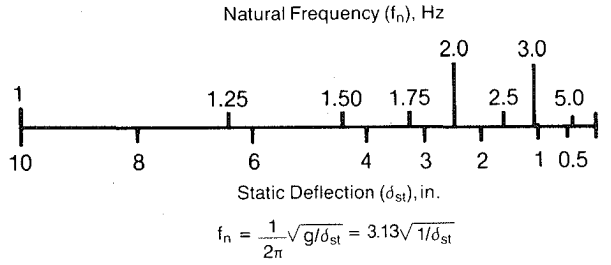

Fig. 11 Natural Frequency of Vibration Isolators

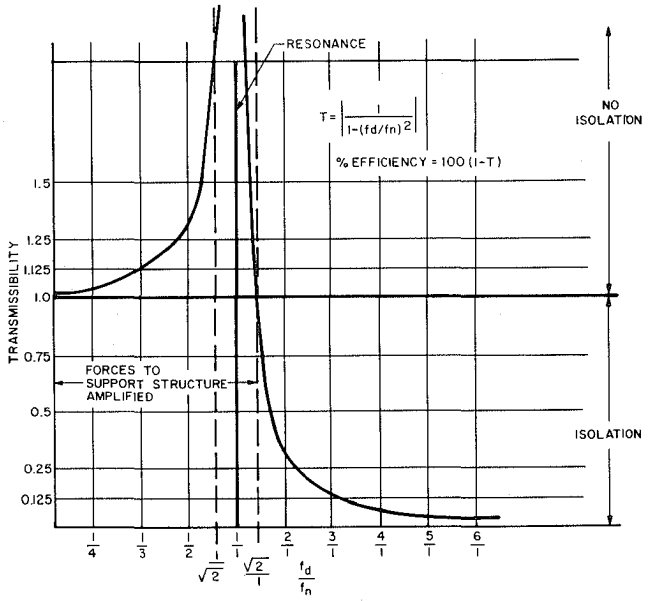

Fig. 12 Vibration Transmissibility as Function of f_d/f_n

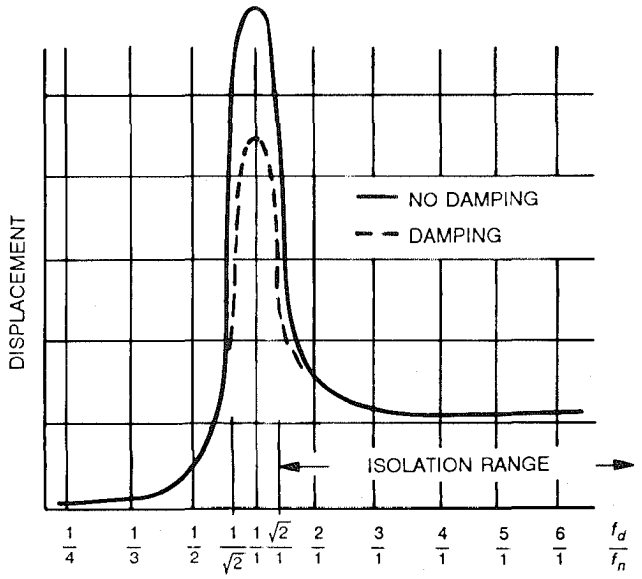

Fig. 13 Displacement of Equipment on Vibration Isolators

some limit to the transmission always occurs because of damping characteristics of isolators and structures. When the isolator natural frequency f_n is lower than the disturbing frequency f_d, isolation occurs (when $f_d/f_n \geq \sqrt{2}$). The transmissibility curve becomes nearly asymptotic above a f_d/f_n ratio of about 5:1, and a large increase in the f_d/f_n ratio is required to reduce the transmissibility further.

Figure 13 plots equipment displacement in accordance with Equation (16). This is similar to the transmissibility curve (Figure 12) in that equipment displacement is very great at resonance and decreases when f_d is greater than f_n and isolation occurs. Note the following:

1. Equipment displacement is greater with isolators than without isolators. Without isolators, displacement is a function of vibratory forces acting against the stiffness of the structure; with isolators, the vibratory forces act against the isolator stiffness, and the isolators are generally not as stiff as the structure.
2. Once in the effective isolation range, the curve flattens out, indicating that the stiffness of the isolator has little effect on equipment displacement. This is because as isolator stiffness decreases, the isolator deflection increases, resulting in a lower natural frequency f_n (see Figure 11). Therefore, as isolator stiffness k decreases, the denominator of Equation (16) increases faster than the numerator, and equipment displacement actually decreases.

The mass of equipment has no effect on transmission through isolators to the structure (Figure 14). As shown, a 1000-lb piece of equipment installed on isolators with stiffness k of 1000 lb_f/in. provides a 1-in. deflection for an isolator natural frequency f_n of 3.13 Hz. If equipment is operated at 564 rpm (9.4 Hz) and develops a force of 100 lb_f, 12.5 lb_f of force is transmitted to the structure. If the mass of the equipment is increased to 10,000 lb and spring stiffness k increased to 10,000 lb_f/in., isolator deflection is still 1 in., resulting in the same 12.5 lb_f force transmitted to the structure. However, the increased mass affects displacement of equipment X. Solving Equation (16) for both sets of conditions results in equipment displacement of 0.0125 in. for a 1000-lb mass, and 0.00125 in. for a 10,000-lb mass. Once in the isolation range, a mass-controlled system is created, where equipment displacement varies linearly with total system mass.

The foregoing discussion assumes an infinitely rigid supporting structure, which is not the case for most upper-floor locations. These can be represented as a two-degree of freedom system shown schematically in Figure 15, where equipment displacement is in accordance with Equation (18).

$$X = \left| \frac{(F/k)\,[1 + (k/k_f) - (f_d/f_f)^2]}{[1 - (f_d/f_n)^2]\,[1 + (k/k_f) - (f_d/f_f)^2] - k/k_f} \right| \quad (18)$$

Floor displacement is in accordance with Equation (19).

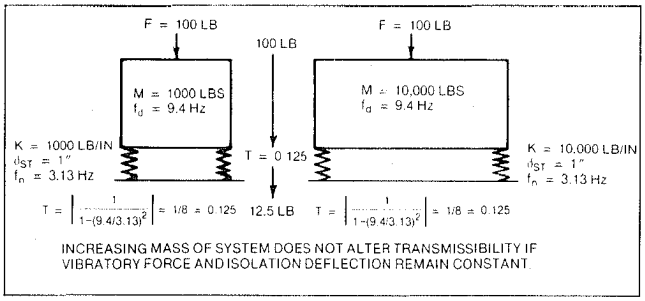
$$X_f = \left| \frac{(F/k_f)}{[1 - (f_d/f_n)^2]\,[1 + (k/k_f) - (f_d/f_f)^2] - k/k_f} \right| \quad (19)$$

Transmissibility at the column supports is shown in Equation (20).

$$T_c = \left| \frac{1}{[1 - (f_d/f_n)^2]\,[1 + (k/k_f) - (f_d/f_f)^2] - k/k_f} \right| \quad (20)$$

The denominator of Equations (18), (19), and (20) is the same; as it approaches zero, resonance occurs, resulting in excessive transmissibility as well as excessive equipment and floor displacement.

Floor stiffness is included in the ratio of isolator stiffness to floor stiffness k/k_f. If total floor deflection and isolator deflection are the same, it does not mean that the floor and the isolators are of equal stiffness. Isolator deflection is a function of equipment mass and isolator stiffness, while floor deflection is a



F = 100 LB

T = 1/(1-(9.4/3.13)²) = 1/8 = 0.125
INCREASING MASS OF SYSTEM DOES NOT ALTER TRANSMISSIBILITY IF VIBRATORY FORCE AND ISOLATION DEFLECTION REMAIN CONSTANT

Fig. 14 Effect of Mass on Transmissibility

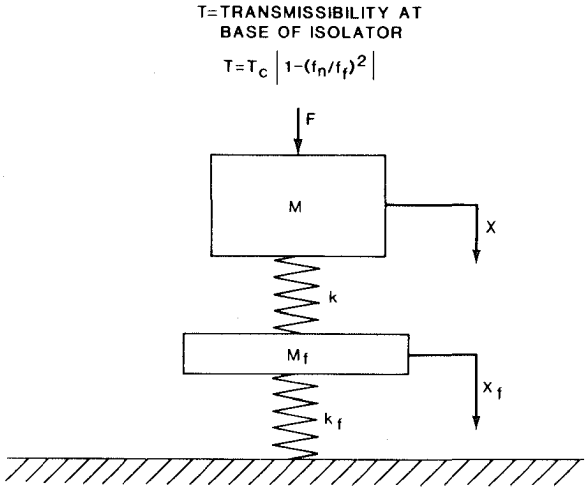

Fig. 15 Two Degrees of Freedom System

function of its own mass and floor spring rate. If the equipment room floor is ten times or more stiff than the spring isolators used to support the equipment, then the ratio of k/k_f becomes so small that it is not significant. Often, this is not the case. For large equipment, refer to Table 34 in Chapter 42 of the 1991 ASHRAE *Handbook—Applications.*

The natural frequency of the floor f_f is critical, because if it is equal or close to the disturbing frequency f_d, a resonant condition exists, resulting in excessive motion of both the equipment and the floor, as well as vibration transmission to the building structure. The natural frequency of the floor is a function of its mass and flexural stiffness, which depends on the material, type of construction, geometry, and support conditions. Floor deflection can indicate potential problems; as floor deflection increases, the fundamental frequency of floor vibration decreases.

If the natural frequency of the floor f_f is not at least three times the disturbing frequency f_d, the possibility of a resonant condition exists, and the following approaches should be considered:

1. Relocate the equipment.
2. Change the operating speed of the equipment to achieve a f_d/f_f ratio of at least 3:1.
3. Stiffen the structure to increase f_f.
4. Increase isolator deflection, thereby decreasing f_n.

Of these options, increasing the isolator deflection is usually the most economical, in which case the selected isolator should provide an f_d/f_n ratio of about 10:1. For example, if f_d is 15 Hz, an isolator with an f_n of about 1.5 Hz is desired, which can be provided by a 4-in. deflection isolation system. In certain situations, especially for large slow-speed equipment operating below 10 Hz, one of the other options might be more useful or cost-effective.

CHAPTER 8

PHYSIOLOGICAL PRINCIPLES AND THERMAL COMFORT

Energy Balance and Thermal Comfort 8.1
Thermal Exchanges with the Environment 8.2
Thermoregulatory Control Mechanisms 8.5
Engineering Data and Measurements 8.7
Environmental Indices 8.12
Prediction of Thermal Comfort and Thermal Sensation 8.16
Special Environments 8.21
Symbols 8.26

THE human body continuously generates heat, with an output varying from about 340 Btu/h for a sedentary person to 3400 Btu/h for a person exercising strenuously. Body temperature must be maintained within a narrow temperature range, to avoid discomfort, and within a somewhat wider range, to avoid danger from heat or cold stress. Consequently, heat must be dissipated in a carefully controlled manner for a body to stay within this range. Heat is not generated uniformly throughout the body, nor is it dissipated uniformly. However, for most engineering applications, it is sufficient to consider the body as a uniform cylinder when describing heat dissipation to the environment (Figure 1).

The total metabolic energy M produced within the body is the metabolic energy required for the person's activity M_{act} plus the metabolic energy required for shivering M_{shiv} (should shivering occur). A portion of the body's energy production may be expended as external work done by the muscles W; the net heat production $M - W$ is either stored, causing the body's temperature to rise, or is dissipated to the environment through the skin surface and respiratory tract. Heat dissipation from the body to the immediate surroundings occurs by several modes of heat exchange: sensible heat flow from the skin $C + R$; latent heat flow from the evaporation of sweat E_{rsw} and from evaporation of moisture diffused through the skin E_{dif}; sensible heat flow during respiration C_{res}; and latent heat flow due to evaporation of moisture during respiration E_{res}. Sensible heat flow from the skin may be a complex mixture of conduction, convection, and radiation for a clothed person; however, it is equal to the sum of the convection C and radiation R heat transfer at the outer clothing surface (or exposed skin).

ENERGY BALANCE AND THERMAL COMFORT

Most models of thermal exchanges between the body and the environment and the subsequent measures of the physiological strain or thermal sensation are similar in that they use classic heat transfer theory as a rational starting basis and introduce empirical equations describing the effects of known physiological regulatory controls. Sensible and latent heat losses from the skin are expressed in terms of environmental factors, skin temperature t_{sk}, and skin wettedness w. The expressions also incorporate factors that account for the thermal insulation and moisture permeability of clothing. The independent environmental variables can be summarized as: air temperature t_a, mean radiant temperature $\bar{t}_r$, relative air velocity v, and ambient water vapor pressure p_a. The independent personal variables that influence thermal comfort are activity and clothing.

The preparation of this chapter is assigned to TC 2.1, Physiology and Human Environment.

Two commonly used models are briefly described here, and more details are given in the section Prediction of Thermal Comfort and Thermal Sensation. Both models assume that skin temperature and skin surface heat transfer are uniform across the body. All terms in Equations (1) and (2) have units of energy per unit area and are referenced to the surface area of the nude body A_D. A correction factor is introduced later to account for the increased surface area of the clothed body A_{cl}. An equation for A_D, referred to as the DuBois surface area, is presented in the Engineering Data and Measurements section.

Steady-State Energy Balance

The steady-state model developed by Fanger (1970, 1982) assumes that the body is in a state of thermal equilibrium with negligible heat storage. The body is assumed to be near thermal neutrality—there is no shivering and vasoregulation is not considered because the core and skin are modeled as one compartment. At steady state, the rate of heat generation equals the rate of heat loss, and the energy balance is:

$$M - W = Q_{sk} + Q_{res} = (C + R + E_{sk}) + (C_{res} + E_{res}) \quad (1)$$

where

M = rate of metabolic heat production, Btu/(h·ft²)
W = rate of mechanical work accomplished, Btu/(h·ft²)
Q_{res} = total rate of heat loss through respiration, Btu/(h·ft²)
Q_{sk} = total rate of heat loss from skin, Btu/(h·ft²)

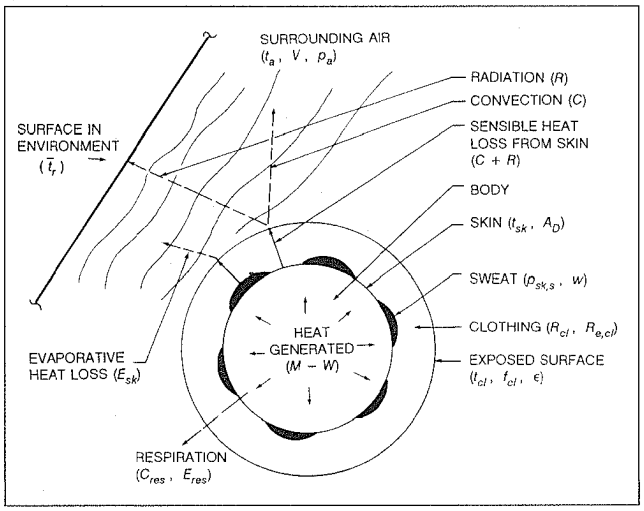

Fig. 1 Cylindrical Model of Thermal Interaction of Human Body and Environment

C_{res} = rate of convective heat loss from respiration, Btu/(h·ft²)
E_{res} = rate of evaporative heat loss from respiration, Btu/(h·ft²)
$C + R$ = sensible heat loss from skin, Btu/(h·ft²)
E_{sk} = rate of total evaporative heat loss from skin [see Equation (13)]

Two-Node, Transient Energy Balance

A two-compartment (or two-node) model developed by Gagge *et al.* (1971, 1986) represents the body as two concentric cylinders—the inner cylinder represents the body core (skeleton, muscle, internal organs), and the outer cylinder represents the skin layer. The model is based on the following assumptions: conductive heat exchange from the skin is negligible; the temperature in each compartment is uniform (core = t_{cr} and skin = t_{sk}); metabolic heat production, external work, and respiratory losses are associated with the core compartment; and the core and skin compartments exchange energy passively through direct contact and through the thermoregulatory controlled peripheral blood flow. A transient energy balance states that the rate of heat storage equals the net rate of heat gain minus the heat loss. The thermal model is described by two coupled heat balance equations, one applied to each compartment:

$$S_{cr} = M - W - (C_{res} + E_{res}) - Q_{cr,sk} \quad (2)$$

$$S_{sk} = Q_{cr,sk} - (C + R + E_{sk}) \quad (3)$$

where

S_{cr} = rate of heat storage in core compartment, Btu/(h·ft²)
S_{sk} = rate of heat storage in skin compartment, Btu/(h·ft²)
$Q_{cr,sk}$ = rate of heat transport from core to skin (includes both conduction through body tissue and convection through blood flow), Btu/(h·ft²)

The rate of heat storage in the body equals the rate of increase in internal energy. The rate of storage can be written separately for each compartment in terms of thermal capacity and time rate of change of temperature in each compartment:

$$S_{cr} = (1 - \alpha)mc_{p,b}(dt_{cr}/d\theta)/A_D \quad (4)$$

$$S_{sk} = \alpha mc_{p,b}(dt_{sk}/d\theta)/A_D \quad (5)$$

where

α = fraction of body mass concentrated in skin compartment, n.d.
m = body mass, lb
$c_{p,b}$ = specific heat capacity of body = 0.834 Btu/(lb·°F)
θ = time, h

The fractional skin mass α depends on the rate of blood flowing to the skin surface $\dot{m}_{bl}$. An empirical equation relating α to $\dot{m}_{bl}$ is presented in the Thermoregulatory Control Mechanisms section.

THERMAL EXCHANGES WITH THE ENVIRONMENT

Fanger (1967, 1970), Hardy (1949), Rapp and Gagge (1967), and Gagge and Hardy (1967) give quantitative information on calculating the heat exchange between people and the environment. A summary of the mathematical statements for various terms of heat exchange used in the heat balance equations (C, R, E_{sk}, C_{res}, E_{res}) follows. Terms describing the heat exchanges associated with the thermoregulatory control mechanisms ($Q_{cr,sk}$, M_{shiv}, E_{rsw}) and values for the coefficients and appropriate equations for M_{act} and A_D are presented in later sections. The mathematical description of the energy balance of the human body represents a combined rational/empirical approach to describing the thermal exchanges with the environment. Fundamental heat transfer theory is used to describe the various mechanisms of sensible and latent heat exchange, while empirical expressions are used to determine the values of the coefficients describing these rates of heat exchange. Empirical equations are also used to describe the thermophysiological control mechanisms as a function of skin and core temperatures in the body.

Sensible Heat Loss from Skin

Sensible heat exchange from the skin surface must pass through clothing to the surrounding environment. These paths are treated in series and can be described in terms of: (1) heat transfer from the skin surface, through the clothing insulation, to the outer clothing surface, and (2) from the outer clothing surface to the environment.

Both convective C and radiative R heat losses from the outer surface of a clothed body can be expressed in terms of a heat transfer coefficient, and the difference between the mean temperature of the outer surface of the clothed body t_{cl} and the appropriate environmental temperature:

$$C = f_{cl}h_c(t_{cl} - t_a) \quad (6)$$

$$R = f_{cl}h_r(t_{cl} - \bar{t}_r) \quad (7)$$

where

h_c = convective heat transfer coefficient, Btu/(h·ft²·°F)
h_r = linear radiative heat transfer coefficient, Btu/(h·ft²·°F)
f_{cl} = clothing area factor = A_{cl}/A_D

The coefficients h_c and h_r are both evaluated at the clothing surface. Equations (6) and (7) are commonly combined to describe the total sensible heat exchange by these two mechanisms in terms of an operative temperature t_o and a combined heat transfer coefficient h:

$$(C + R) = f_{cl}h(t_{cl} - t_o) \quad (8)$$

where

$$t_o = (h_r\bar{t}_r + h_c t_a)/(h_r + h_c) \quad (9)$$

$$h = h_r + h_c \quad (10)$$

Based on Equation (9), operative temperature t_o can be defined as the average of the mean radiant and ambient air temperatures, weighted by their respective heat transfer coefficients.

The actual transport of sensible heat through clothing involves conduction, convection, and radiation. It is usually most convenient to combine these into a single thermal resistance value R_{cl}, defined by:

$$(C + R) = (t_{sk} - t_{cl})/R_{cl} \quad (11)$$

where R_{cl} = thermal resistance of clothing, h·ft²·°F/Btu.

Since it is often inconvenient to include the clothing surface temperature in calculations, Equations (8) and (11) can be combined to eliminate t_{cl}:

$$(C + R) = (t_{sk} - t_o)/[R_{cl} + 1/(f_{cl}h)] \quad (12)$$

where t_o is defined in Equation (9).

Evaporative Heat Loss from Skin

Evaporative heat loss from skin E_{sk} depends on the difference between the water vapor pressure at the skin and in the ambient environment, and the amount of moisture on the skin:

$$E_{sk} = w(p_{sk,s} - p_a)/[R_{e,cl} + 1/(f_{cl}h_e)] \quad (13)$$

where

p_a = water vapor pressure in ambient air, psi
$p_{sk,s}$ = water vapor pressure at skin, normally assumed to be that of saturated water vapor at t_{sk}, psi
$R_{e,cl}$ = evaporative heat transfer resistance of clothing layer (analogous to R_{cl}), ft²·psi·h/Btu
h_e = evaporative heat transfer coefficient (analogous to h_c), Btu/(h·ft²·psi)
w = skin wettedness, dimensionless

Procedures for calculating $R_{e,cl}$ and h_e are given in the Engineering Data and Measurements section. Skin wettedness is the ratio of the actual evaporative heat loss to the maximum possible evaporative heat loss E_{max} with the same conditions and a completely wetted skin ($w = 1$). The value of skin wettedness is important in determining evaporative heat loss. Maximum evaporative potential E_{max} occurs when the skin surface is completely wetted, or $w = 1.0$.

Evaporative heat loss from the skin is a combination of the evaporation of sweat secreted due to thermoregulatory control mechanisms E_{rsw} and the natural diffusion of water through the skin E_{dif}:

$$E_{sk} = E_{rsw} + E_{dif} \quad (14)$$

Evaporative heat loss by regulatory sweating is directly proportional to the regulatory sweat generated:

$$E_{rsw} = \dot{m}_{rsw} h_{fg} \quad (15)$$

where

h_{fg} = heat of vaporization of water = 1045 Btu/lb at 86°F
$\dot{m}_{rsw}$ = rate at which regulatory sweat is generated, lb/h·ft² [see Equation (45)]

The portion of a body that must be wetted to evaporate the regulatory sweat w_{rsw} is:

$$w_{rsw} = E_{rsw}/E_{max} \quad (16)$$

With no regulatory sweating, skin wettedness due to diffusion is approximately 0.06 for normal conditions. For large values of E_{max} or long exposures to low humidities, the value may drop to as low as 0.02, since dehydration of the outer skin layers alters its diffusive characteristics. With regulatory sweating, the 0.06 value applies only to the portion of skin not covered with sweat $(1 - w_{rsw})$; the diffusion evaporative heat loss is:

$$E_{dif} = (1 - w_{rsw})\, 0.06\, E_{max} \quad (17)$$

These equations can be solved to give a value of w, given the maximum evaporative potential E_{max} and the regulatory sweat generation E_{rsw}:

$$w = w_{rsw} + 0.06\,(1 - w_{rsw}) = 0.06 + 0.94\, E_{rsw}/E_{max} \quad (18)$$

Once skin wettedness is determined, evaporative heat loss from the skin is calculated from Equation (13), or by:

$$E_{sk} = wE_{max} \quad (19)$$

To summarize, the following calculations determine w and E_{sk}:

E_{max}	Equation (13), with $w = 1.0$
E_{rsw}	Equation (15)
w	Equation (18)
E_{sk}	Equation (19) or (13)

Although evaporation from the skin E_{sk} as described in Equation (13) depends on w, the body does not directly regulate skin wettedness but, rather, regulates sweat rate $\dot{m}_{rsw}$ [Equation (15)]. Skin wettedness is then an indirect result of the relative activity of the sweat glands and the evaporative potential of the environment. Skin wettedness of 1.0 is the upper theoretical limit. If the aforementioned calculations yield a wettedness of more than 1.0, then Equation (15) is no longer valid since all of the sweat is not evaporated. In this case, $E_{sk} = E_{max}$.

Skin wettedness is strongly correlated with warm discomfort and is also a good measure of thermal stress. Theoretically, skin wettedness can approach 1.0 while the body still maintains thermoregulatory control. In most situations, it is difficult to exceed 0.8. Azer (1982) recommends 0.5 as a practical upper limit for sustained activity for a healthy acclimatized person.

Respiratory Losses

During respiration, the body loses both sensible and latent heat by convection and evaporation of heat and water vapor from the respiratory tract to the inhaled air. A significant amount of heat can be associated with respiration because the air is inspired at ambient conditions and expired nearly saturated at a temperature only slightly cooler than t_{cr}.

Sensible C_{res} and latent E_{res} heat losses due to respiration are:

$$C_{res} = \dot{m}_{res} c_{p,a} (t_{ex} - t_a)/A_D \quad (20)$$

$$E_{res} = \dot{m}_{res} h_{fg} (W_{ex} - W_a)/A_D \quad (21)$$

where

$\dot{m}_{res}$ = pulmonary ventilation rate, lb/h
t_{ex} = temperature of exhaled air, °F
W_{ex} = humidity ratio of exhaled air, lb H_2O/lb d.a.
W_a = humidity ratio of inhaled (ambient) air, lb H_2O/lb d.a.
$c_{p,a}$ = specific heat of air, Btu/(lb·°F)

These equations can be reduced by using approximations and empirical relationships to estimate the values of the parameters. Under normal circumstances, pulmonary ventilation rate is primarily a function of metabolic rate (Fanger 1970):

$$\dot{m}_{res} = K_{res} M \quad (22)$$

where K_{res} is a proportionality constant (0.0645 lb·ft²/Btu).

Respiratory air is nearly saturated and near the body temperature when exhaled. The following empirical equations developed by Fanger (1970) can be used to estimate these conditions for typical indoor environments:

$$t_{ex} = 88.6 + 0.066\, t_a + 57.6\, W_a \quad (23)$$

$$W_{ex} - W_a = 0.0265 + 0.000036\, t_a - 0.80\, W_a \quad (24)$$

where t_a and t_{ex} are in °F. For more extreme conditions, such as outdoor winter environments, different relationships may be required (see Holmer 1984).

The humidity ratio of ambient air can be expressed in terms of the total or barometric pressure p_t and ambient partial vapor pressure p_a:

$$W_a = 0.622\, p_a/(p_t - p_a) \quad (25)$$

Two approximations are commonly used to simplify Equations (20) and (21). First, because the dry respiratory heat loss is relatively small compared to the other terms in the heat balance, an average value for t_{ex} is determined by evaluating Equation (23) at

standard conditions (68 °F, 50% rh, sea level). Second, noting in Equation (24) that there is only a weak dependence on ambient air temperature, the second term in Equation (24) and the denominator in Equation (25) are evaluated at standard conditions. Using these approximations, and substituting values of h_{fg} and $c_{p,a}$ at standard conditions, Equations (20) and (21) can be combined and written as:

$$C_{res} + E_{res} = [0.0084M(93.2 - t_a) + 1.28M(0.851 - p_a)]/A_D \quad (26)$$

where p_a is expressed in psi and t_a is in °F.

Alternative Formulations

Equations (12) and (13) describe heat loss from skin for clothed people in terms of clothing parameters R_{cl}, $R_{e,cl}$, and f_{cl}; parameters h and h_e describe outer surface resistances. Other parameters and definitions are also used. Although these alternate parameters and definitions may be confusing, note that the information presented in one form can be converted to another form. Common parameters and their qualitative descriptions are presented in Table 1. Equations showing their relation to each other are presented in Table 2. Generally, parameters related to dry or evaporative heat flows are not independent because they both rely, in part, on the same physical processes. The Lewis relation describes the relations between convective heat transfer and mass transfer coefficients for a surface (see Chapter 5). The Lewis relation can be used to relate convective and evaporative heat transfer coefficients defined in Equations (4) and (11) according to:

$$h_e/h_c = \text{LR} \quad (27)$$

where LR is referred to as the "Lewis ratio" and, at typical indoor conditions, equals approximately 205 °F/psi. The Lewis relation applies to surface convection coefficients. Heat transfer coefficients that include the effects of insulation layers and/or radiation will still be coupled, but the relationship may deviate significantly from that for a surface. The i terms in Tables 1 and 2 describe how the actual ratios of these parameters deviate from the ideal Lewis ratio (Woodcock 1962, Oohori 1985).

Depending on the combination of parameters used, heat transfer from the skin can be calculated using several different formulations (see Table 3). If the parameters are used correctly, the end result will be the same regardless of the formulation used.

Total Skin Heat Loss

Total skin heat loss—sensible heat plus evaporative heat—can be calculated from any combination of the equations presented in Table 3. Total skin heat loss is used as a measure of the thermal environment; two combinations of parameters that yield the same total heat loss for a given set of body conditions (t_{sk} and w) are considered to be approximately equivalent. The fully expanded skin heat loss equation, showing each parameter that must be known or specified, is as follows:

$$Q_{sk} = \frac{t_{sk} - \dfrac{\bar{t}_r h_r + t_a h_c}{h_r + h_c}}{R_{cl} + \dfrac{1}{[(h_r + h_c) f_{cl}]}} + w \frac{p_{sk,s} - p_a}{R_{e,cl} + \dfrac{1}{(\text{LR} h_c f_{cl})}} \quad (28)$$

or

$$Q_{sk} = F_{cl} f_{cl} h + w\text{LR} F_{pcl} h_c \quad (29)$$

This equation allows the trade-off between any two, or more, parameters to be evaluated under given conditions. If the trade-off between two specific variables is to be examined, then a simplified form of the equation suffices. The trade-off between operative temperature and humidity is often of interest. Equation (28) can be written in a much simpler form for this purpose (Fobelets and Gagge 1988):

$$Q_{sk} = h' [(t_{sk} + wi_m \text{LR} p_{sk,s}) - (t_o + wi_m \text{LR} p_a)] \quad (30)$$

Equation (30) can be used to define a combined temperature t_{com}, which reflects the combined effect of operative temperature and humidity for an actual environment:

Table 1 Parameters Used to Describe Clothing

Sensible Heat Flow

- R_{cl} = instrinsic clothing insulation, the thermal resistance of a uniform layer of insulation covering the entire body that has the same effect on sensible heat flow as the actual clothing.
- R_t = total insulation, the total equivalent uniform thermal resistance between the body and the environment: clothing and boundary resistance.
- R_{cle} = effective clothing insulation, the increased body insulation due to clothing as compared to the nude state.
- R_a = boundary insulation, the thermal resistance at the skin boundary for a nude body.
- $R_{a,cl}$ = outer boundary insulation, the thermal resistance at the outer boundary (skin or clothing).
- h' = overall sensible heat transfer coefficient, the overall equivalent uniform conductance between the body and the environment.
- h'_{cl} = clothing conductance, the thermal conductance of a uniform layer of insulation covering the entire body that has the same effect on sensible heat flow as the actual clothing.
- F_{cle} = effective clothing thermal efficiency, the ratio of the actual sensible heat loss to that of a nude body at the same conditions.
- F_{cl} = intrinsic clothing thermal efficiency, the ratio of the actual sensible heat loss to that of a nude body at the same conditions including an adjustment for the increase in surface area due to the clothing.

Evaporative Heat Flow

- $R_{e,cl}$ = evaporative heat transfer resistance of the clothing, the impedance to transport of water vapor of a uniform layer of insulation covering the entire body that has the same effect on evaporative heat flow as the actual clothing.
- $R_{e,t}$ = total evaporative resistance, the total equivalent uniform impedance to the transport of water vapor from the skin to the environment.
- F_{pcl} = permeation efficiency, the ratio of the actual evaporative heat loss to that of a nude body at the same conditions, including an adjustment for the increase in surface area due to the clothing.

Parameters Relating Sensible and Evaporative Heat Flow

- i_{cl} = clothing vapor permeation efficiency, the ratio of the actual evaporative heat flow capability through the clothing to the sensible heat flow capability as compared to the Lewis ratio.
- i_m = moisture permeability index, the ratio of the actual evaporative heat flow capability between the skin and the environment to the sensible heat flow capability as compared to the Lewis ratio.
- i_a = air layer vapor permeation efficiency, the ratio of the actual evaporative heat flow capability through the outer air layer to the sensible heat flow capability as compared to the Lewis ratio.

Table 2 Relationships between Clothing Parameters

Sensible Heat Flow

$$R_t = R_{cl} + 1/(h f_{cl}) = R_{cl} + R_a/f_{cl}$$
$$R_t = R_{clc} + 1/h = R_{clc} + R_a$$
$$h'_{cl} = 1/R_{cl}$$
$$h' = 1/R_t$$
$$h = 1/R_a$$
$$R_{a,cl} = R_a/f_{cl}$$
$$F_{cl} = h'/(h f_{cl}) = 1/(1 + f_{cl} h R_{cl})$$
$$F_{clc} = h'/h = f_{cl}/(1 + f_{cl} h R_{cl}) = f_{cl} F_{cl}$$

Evaporative Heat Flow

$$R_{e,t} = R_{e,cl} + 1/(h_e f_{cl}) = R_{e,cl} + R_{e,a}/f_{cl}$$
$$h_e = 1/R_{e,a}$$
$$h'_{e,cl} = 1/R_{e,cl}$$
$$h'_e = 1/R_{e,t} = f_{cl} F_{pcl} h_e$$
$$F_{pcl} = 1/(1 + f_{cl} h_e R_{e,cl})$$

Parameters Relating Sensible and Evaporative Heat Flows

$$i_{cl}\mathrm{LR} = h'_{e,cl}/h'_{cl} = R_{cl}/R_{e,cl}$$
$$i_m\mathrm{LR} = h'_e/h' = R_t/R_{e,t}$$
$$i_m = (R_{cl} + R_{a,cl})/[(R_{cl}/i_{cl}) + (R_{a,cl}/i_a)]$$
$$i_a\mathrm{LR} = h_e/h$$
$$i_a = h_c/(h_c + h_r)$$

Table 3 Skin Heat Loss Equations

Sensible Heat Loss

$$C + R = (t_{sk} - t_o)/[R_{cl} + 1/(f_{cl} h)]$$
$$C + R = (t_{sk} - t_o)/R_t$$
$$C + R = F_{clc} h (t_{sk} - t_o)$$
$$C + R = F_{cl} f_{cl} h (t_{sk} - t_o)$$
$$C + R = h' (t_{sk} - t_o)$$

Evaporative Heat Loss

$$E_{sk} = w (p_{sk,s} - p_a)/[R_{e,cl} + 1/(f_{cl} h_e)]$$
$$E_{sk} = w (p_{sk,s} - p_a)/R_{e,t}$$
$$E_{sk} = w F_{pcl} f_{cl} h_e (p_{sk,s} - p_a)$$
$$E_{sk} = h'_e w (p_{sk,s} - p_a)$$
$$E_{sk} = h' w_{im}\,\mathrm{LR} (p_{sk,s} - p_a)$$

$$t_{com} + w i_m \mathrm{LR} p (t_{com}) = t_o + w i_m \mathrm{LR} p_a$$

or

$$t_{com} = t_o + w i_m \mathrm{LR} p_a - w i_m \mathrm{LR} p (t_{com}) \quad (31)$$

where $p(t_{com})$ is a vapor pressure related in some fixed way to t_{com} and is analogous to $p_{wb,s}$ for t_{wb}. The term $w i_m \mathrm{LR} p(t_{com})$ is constant, to the extent that i_m is constant and any combination of t_o and p_a that gives the same t_{com} will result in the same total heat loss.

Environmental indices are discussed in a later section of this chapter. Two of these, the humid operative temperature t_{oh} and the effective temperature ET*, can be represented in terms of Equation (31). The humid operative temperature is that temperature which at 100% rh yields the same total heat loss as for the actual environment:

$$t_{oh} = t_o + w i_m \mathrm{LR} (p_a - p_{oh,s}) \quad (32)$$

where $p_{oh,s}$ = saturated vapor pressure at t_{oh}, psi.

The effective temperature is the temperature at 50% rh that yields the same total heat loss as for the actual environment:

$$\mathrm{ET^*} = t_o + w i_m \mathrm{LR} (p_a - 0.5\, p_{\mathrm{ET^*},s}) \quad (33)$$

where $p_{\mathrm{ET^*},s}$ = saturated vapor pressure at ET*, psi.

The psychrometric chart in Figure 2 shows a constant total heat loss line and the relationship between these indices. This line represents only one specific skin wettedness and moisture permeability index. The relationship between indices depends on these two parameters (see the Environmental Indices section).

THERMOREGULATORY CONTROL MECHANISMS

Zones of Physiological and Behavioral Response

Heat exchange exists in relation to zones of different physiological and behavioral response. In the operative temperature range from 84 to 88 °F for unclothed, and 73 to 81 °F for normally clothed, sedentary people (0.6 clo), there is no body cooling or heating and no increase in evaporative heat loss. Within this zone, each individual has a neutral temperature where the environment is neither hot nor cold, and where no action from the physiological control system is required to maintain normal body temperature. If the rate of heat loss from skin to environment increases, the body decreases blood flow to the skin. This cools the skin and subjacent tissues and maintains the temperature of deep tissues. The external conditions over which this occurs fall in a narrow range called the *zone of vasomotor regulation against cold.* Below this range, temperatures of superficial and deep tissues fall, unless another control reaction occurs. Typically, the body generates heat through muscular tension, shivering, or spontaneous activity. If the heat generated balances the increased heat loss to the environment, deep body temperature is maintained. An alternative control reaction in the *zone of behavioral regulation against cold* involves donning more clothing or increasing activity (*e.g.*, walking faster). If all control reactions prove inadequate, the body enters the *zone of body cooling.* When core temperature falls below 95 °F, people suffer major losses in efficiency (*e.g.*, in manual dexterity under arctic conditions); core temperatures below 87.8 °F can be lethal.

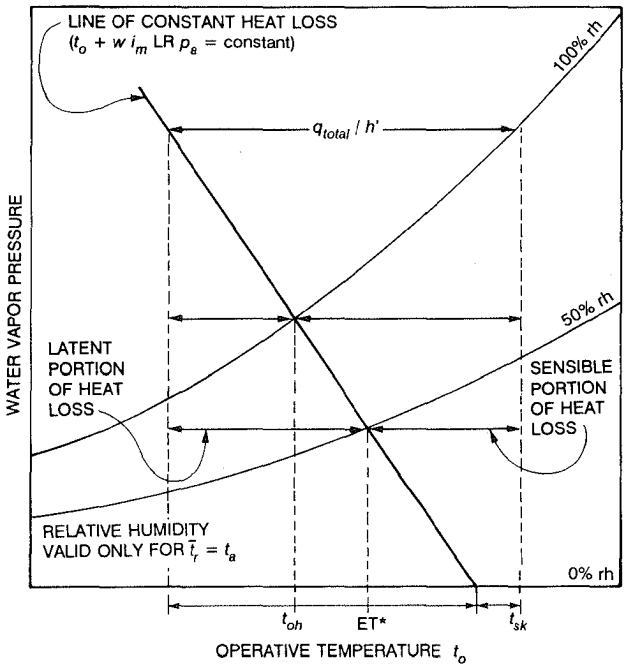

Fig. 2 Constant Heat Loss Line and Its Relationship to t_{oh} and ET*

Over a wide range of cold external conditions, the body adjusts by providing life-sustaining conditions for crucial internal regions at the expense of an energy loss from and possible damage to peripheral tissues. The farther the superficial tissues (*e.g.*, hands and feet) are from the central body mass, the more readily their temperatures fall. The larger the surface area per unit of thermal mass (*e.g.*, ears versus torso), the more rapidly its temperature falls.

On the hot side of the neutral midpoint is a narrow *zone of vasomotor regulation against heat.* Physiological control mechanisms for this zone correspond to those used against cold. Blood flow to the skin increases when desirable heat loss to the environment is restricted. This increase in blood flow can double or triple the conductance of heat to superficial tissues over that characteristic of the neutral point, causing skin surface temperature to come closer to the temperature of the deep tissues. If, in spite of this increase in blood flow, the core temperature rises above 98.6°F, the body enters its second line of defense, releasing water from sweat glands for evaporative cooling. As long as this cooling can maintain required heat loss, the body is in the *zone of evaporative regulation.* Therefore, any environmental factor that affects evaporation of water from the skin affects temperature regulation. For example, increased atmospheric water vapor pressure, reduced air movement, and added clothing all affect the upper limit of E_{sk}. When this cooling is inadequate, the body is in the *zone of body heating.* When the core temperature rises above 102.2°F, people suffer major losses in efficiency (become sluggish or refuse to contine their present exertion level). Deep body temperatures above 109°F can be lethal.

Regulatory Signals and Responses

The following discussion is based on the two-node model (Gagge *et al.* 1971); other, more complex sets of control relationships have also been developed for other models (see Hardy 1961, for example). When the body is able to maintain its thermal equilibrium with the environment with minimal regulatory effort, it is in a state of physiological thermal neutrality, *i.e.*, the average core and skin temperatures are at their neutral values:

$$t_{sk,n} = 92.7\,°\text{F} \tag{34}$$

$$t_{cr,n} = 98.2\,°\text{F} \tag{35}$$

Empirical relationships derived from laboratory experiments describe how the thermoregulatory control processes (vasomotor regulation, sweating, and shivering) are probably stimulated and governed by temperature signals from the skin and core (deviations from their respective neutral set points). Five signals trigger these processes: warm signal from the core (WSIG_{cr}), cold signal from the core (CSIG_{cr}), warm signal from the skin (WSIG_{sk}), cold signal from the skin (CSIG_{sk}), and warm signal from the body (WSIG_{b}). The signals are written in terms of actual temperature t, and neutral temperature t_n, such that they only take on positive values:

$$\text{WSIG}_{cr} = \begin{cases} 0 & t_{cr} \leqslant t_{cr,n} \\ t_{cr} - t_{cr,n} & t_{cr} > t_{cr,n} \end{cases} \tag{36}$$

$$\text{CSIG}_{cr} = \begin{cases} t_{cr,n} - t_{cr} & t_{cr} < t_{cr,n} \\ 0 & t_{cr} \geqslant t_{cr,n} \end{cases} \tag{37}$$

$$\text{WSIG}_{sk} = \begin{cases} 0 & t_{sk} \leqslant t_{sk,n} \\ t_{sk} - t_{sk,n} & t_{sk} > t_{sk,n} \end{cases} \tag{38}$$

$$\text{CSIG}_{sk} = \begin{cases} t_{sk,n} - t_{sk} & t_{sk} < t_{sk,n} \\ 0 & t_{sk} \geqslant t_{sk,n} \end{cases} \tag{39}$$

$$\text{WSIG}_{b} = \begin{cases} 0 & t_{b} \leqslant t_{b,n} \\ t_{b} - t_{b,n} & t_{b} > t_{b,n} \end{cases} \tag{40}$$

The average temperature of the human body t_b can be predicted by the weighted average of the skin and core temperatures:

$$t_b = \alpha t_{sk} + (1 - \alpha)\, t_{cr} \tag{41}$$

The neutral body temperature $t_{b,n}$ is calculated from the neutral skin and core temperature in the same manner. The value of the weighting coefficient α depends on the rate of blood flow to the skin; an empirical relationship between α and $\dot{m}_{bl}$ is presented in Equation (44). In the two-compartment thermal model, α represents the fraction of the total body mass concentrated in the skin compartment.

The following empirical equations are introduced into the Pierce two-node heat balance model of the human body. They are not used in the Fanger whole-body steady-state model, because that model does not independently calculate t_{sk} and t_{cr}.

Skin blood flow and heat transport. Vasomotor activity is controlled by warm and cold temperature signals from the core and skin, respectively. Normal blood flow for sedentary activity at thermally neutral body conditions is approximately 1.29 lb/(h·ft²), expressed per unit DuBois surface area. Vasodilation is governed by warm signals from the core. For each 1°F increase above $t_{cr,n}$, blood flow increases by 41 lb/(h·ft²). Warm signals from the skin play a more important role in body temperature regulation by governing sweating rather than vasodilation, and hence its effect on dilation is neglected. Vasoconstriction is governed by cold signals from the skin, and for each one degree decrease below $t_{sk,n}$, blood flow encounters a proportional increase in resistance. This resistance factor varies throughout the body (*i.e.*, it is high in the hands and feet, negligible in the trunk) and its effect is given an average value. A cold signal from the core causes vasoconstriction, but not as rapidly or effectively as a cold signal from the skin, and its effect is consequently neglected. The effects of core and skin temperature deviations on blood flow can be expressed mathematically as:

$$\dot{m}_{bl} = 0.205\,[(11.3 + 200\,\text{WSIG}_{cr})/(1.8 + 0.5\,\text{CSIG}_{sk})] \tag{42}$$

Blood flow is limited to the range: $0.10 < \dot{m}_{bl} < 18$ lb/(h·ft²).

In the two-compartment model, heat is transferred from the core to the skin passively (by direct contact), and through the skin blood flow, which is controllable. The combined thermal exchange between the core and skin can be written as:

$$Q_{cr,sk} = (K + c_{p,bl}\,\dot{m}_{bl})\,(t_{cr} - t_{sk}) \tag{43}$$

where

K = effective conductance between core and skin
= 0.930 Btu/(h·ft²·°F)

$c_{p,bl}$ = specific heat capacity of blood = 1.00 Btu/(lb·°F)

Fractional skin mass. Changes in $\dot{m}_{bl}$ influence the effective masses of the skin and core compartments by effectively changing the thermal resistance of the skin layers and the depth of the temperature gradient from the skin surface to the internal core. Since the Pierce two-compartment model assumes that each compartment is of a uniform temperature, this is equivalent to chang-

ing the apparent fractional mass of the skin compartment. For example, in cold environments, blood flow to the skin lowers and the skin and fat become isolated from the core. The actual body mass approximated by t_{cr} is therefore smaller and α increases. The effect of blood flow on the relative masses of the skin and core compartments can be written as:

$$\alpha = 0.0418 + 0.745/(4.89\dot{m}_{bl} + 0.585) \quad (44)$$

During thermal equilibrium and while sedentary, $\alpha \cong 0.2$. With exercise or overheating, circulation to the extremities increases and the skin layer becomes more closely coupled to the core, producing a value of $\alpha \cong 0.1$. When the body is exposed to cold, circulation to the extremities decreases and the skin layer becomes less closely coupled to the core, resulting in a higher value of $\alpha \cong 0.33$. As indicated in Equation (42), $\dot{m}_{bl}$ and, consequently, α are both determined by the deviations of t_{cr} and t_{sk} from their neutral values.

Regulatory sweating. The activity of the sweat glands is activated by warm signals from both the core and the skin, and is expressed in terms of the warm signal from the weighted average body temperature and a local control factor at the skin:

$$\dot{m}_{rsw} = 0.019\,\mathrm{WSIG}_b \exp(\mathrm{WSIG}_{sk}/19.3) \quad (45)$$

The value of $\dot{m}_{rsw}$ [calculated in Equation (45)] is then used to determine E_{rsw} in Equation (15).

Shivering. Generating additional metabolic heat through shivering and muscle tension is a more effective mechanism for maintaining the body's heat balance in extremely cold weather than vasoconstriction of the blood vessels. Shivering can raise M as much as three times its normal sedentary value. Metabolic energy production due to shivering requires simultaneous cold signals from both the skin and core, and is related to the two signals by the expression:

$$M_{shiv} = 1.90\,\mathrm{CSIG}_{sk}\,\mathrm{CSIG}_{cr} \quad (46)$$

The total metabolic energy M is then the sum of the shivering energy M_{shiv} and the metabolic heat generated due to activity M_{act}:

$$M = M_{act} + M_{shiv} \quad (47)$$

The following section describes the estimation of M_{act} in more detail.

ENGINEERING DATA AND MEASUREMENTS

Applying the preceding basic equations to practical problems of the thermal environment requires quantitative estimates of the body's surface area, metabolic requirements for a given activity and the mechanical efficiency for the work accomplished, evaluation of the heat transfer coefficient h_r and h_c, and the general nature of the clothing insulation used. This section provides the necessary data and describes methods used to measure the parameters of the heat balance equation.

Body Surface Area

The terms in the heat balance equations previously presented have units of energy per unit area and refer to the surface area of the nude body. The most useful measure of nude body surface area, originally proposed by DuBois (1916), is described by:

$$A_D = 0.108\, m^{0.425}\, l^{0.725} \quad (48)$$

where

A_D = DuBois surface area, ft^2
m = mass, lb
l = height, in.

A correction factor $f_{cl} = A_{cl}/A_D$ must be applied to the heat transfer terms from the skin (C, R, and E_{sk}) to account for the actual surface area of the clothed body A_{cl}. This factor can be found in Table 7 for various clothing ensembles. For an average sized man, 68 in. and 154 lb, $A_D = 19.6$ ft^2. All terms in the basic heat balance equations are expressed per unit DuBois surface area.

Metabolic Rate and Mechanical Efficiency

Maximum energy capacity. In choosing optimal conditions for comfort and health, the energy expended during routine physical activities must be known, because metabolic energy production increases in proportion to exercise intensity. Metabolic rate varies over a wide range, depending on the activity, the person, and the conditions under which the activity is performed. Table 4 lists typical metabolic rates for an average adult ($A_D = 19.6$ ft^2) for activities performed continuously. The highest energy level a

Table 4 Typical Metabolic Heat Generation for Various Activities

	Btu/(h·ft^2)	met[a]
Resting		
Sleeping	13	0.7
Reclining	15	0.8
Seated, quiet	18	1.0
Standing, relaxed	22	1.2
Walking (on level surface)

Calisthenics/exercise	55 to 74	3.0 to 4.0
Tennis, singles	66 to 74	3.6 to 4.0
Basketball	90 to 140	5.0 to 7.6
Wrestling, competitive	130 to 160	7.0 to 8.7

Compiled from various sources. For additional information, see Buskirk (1960), Passmore and Durnin (1967), and Webb (1964).
[a] 1 met = 18.43 Btu/(h·ft^2)

person can maintain for any continuous length of time is approximately 50% of the maximal capacity to use oxygen (maximum energy capacity).

A unit used to express the metabolic rate per unit DuBois area is the met, defined as the metabolic rate of a sedentary person (seated, quiet): 1 met = 18.43 Btu/(h·ft²). A normal, healthy man has a maximum energy capacity of approximately M_{act} = 12 met at age 20, which drops to 7 met at age 70. Maximum rates for women are about 30% lower. Long-distance runners and trained athletes have maximum rates as high as 20 met. An average 35 year-old that does not exercise has a maximum rate of about 10 met and activities with $M_{act} > 5$ met are likely to prove exhausting.

Intermittent activity. The activity of many people consists of a mixture of activities or a combination of work-rest periods. A weighted average metabolic rate is generally satisfactory, provided that activities alternate frequently (several times per hour). For example, a person typing 50% of the time, filing while seated 25% of the time, and walking about 25% of the time would have an average metabolic rate of 0.50 × 20 + 0.25 × 22 + 0.25 × 31 = 23 Btu/(h·ft²) (see Table 4).

Accuracy. Estimating metabolic rates is difficult. The values given in Table 4 only indicate metabolic rates for the specific activities listed. Some entries give a range and some a single value, depending on the source of the data. The level of accuracy depends on the value of M_{act} and how well the activity can be defined. For well-defined activities with $M_{act} < 1.5$ met (*e.g.*, reading), Table 4 is sufficiently accurate for most engineering purposes. For values of $M_{act} > 3$, where a task is poorly defined or where there are a variety of ways of performing a task (*e.g.*, heavy machine work), the values may be in error by as much as ±50% for a given application. Engineering calculations should thus allow for potential variations.

Measurement. When metabolic rates must be determined more accurately than is possible with tabulated data, physiological measurements with human subjects may be necessary. The rate of metabolic heat produced by the body is most accurately measured by the rate of respiratory oxygen consumption and carbon dioxide production. An empirical equation for metabolic rate is given by Nishi (1981):

$$M = 567\,(0.23\,RQ + 0.77)\,V_{O_2}/A_D, \text{ in Btu/(h·ft}^2\text{)} \qquad (49)$$

where

RQ = respiratory quotient; molar ratio of V_{CO_2} exhaled to V_{O_2} inhaled, dimensionless
V_{O_2} = volumetric rate of oxygen consumption at conditions (STPD) of 32°F, 14.7 psi, ft³/h

The exact value of the respiratory quotient used in Equation (49) RQ depends on a person's activity, diet, and physical condition. It can be determined by measuring both carbon dioxide and oxygen in the respiratory airflows, or it can be estimated with reasonable accuracy. A good estimate for the average adult is RQ = 0.83 for light or sedentary activities ($M < 1.5$ met), increasing proportionately to RQ = 1.0 for heavy exertion ($M = 5.0$ met). In extreme cases, the maximum range is $0.7 < RQ < 1.0$. Estimation of RQ is generally sufficient for all except precision laboratory measurements since it does not strongly affect the value of the metabolic rate. A 10% error in estimating the respiratory quotient results in an error of less than 3% in the metabolic rate.

A second, much less accurate, method of estimating metabolic rate physiologically is to measure the heart rate. Table 5 shows the relationship between heart rate and oxygen consumption at different levels of physical exertion for a typical person. Once oxygen consumption is estimated from heart rate information, Equation (49) can be used to estimate the metabolic rate. A number of factors other than metabolic rate affect heart rate, such as physical condition, heat, emotional factors, muscles used, etc. Astrand and Rodahl (1977) show that heart rate is only a very approximate measure of metabolic rate and should not be the only source of information where accuracy is required.

Table 5 Heart Rate and Oxygen Consumption at Different Activity Levels[a]

Level of Exertion	Oxygen Consumed, ft³/h	Heart Rate, beat/min
Light work	< 0.1	< 90
Moderate work	1.0 to 2.0	90 to 110
Heavy work	2.0 to 3.0	110 to 130
Very heavy work	3.0 to 4.0	130 to 150
Extremely heavy work	> 4.0	150 to 170

[a]Astrand and Rodahl (1977).

Mechanical efficiency. In the heat balance equation, the rate of work accomplished W must be in the same units as metabolism M and expressed in terms of A_D in Btu/(h·ft²). The mechanical work done by the muscles for a given task is often expressed in terms of the body's mechanical efficiency $\mu = W/M$. It is unusual for μ to be more than 5 to 10%; for most activities, it is close to zero. The maximum value under optimal conditions (*e.g.*, bicycle ergometer) is μ = 20 to 24% (Nishi 1981). It is common to assume that mechanical work is zero for several reasons: (1) the mechanical work produced is small compared to metabolic rate, especially for office activities; (2) estimates for metabolic rates can often be inaccurate; and (3) this assumption results in a more conservative estimate when designing air-conditioning equipment for upper comfort and health limits. More accurate calculation of heat generation may require estimation of the mechanical work produced for activities where it is significant (walking on a grade, climbing a ladder, bicycling, lifting, etc.). In some cases, it is possible to either estimate or measure the mechanical work. For example, a 200-lb person walking up a 5% grade at 4.4 ft/s (3 mph) would lift a 200-lb weight a height of 0.22 ft every second, for a work rate of 44 ft·lb$_f$/s, or 204 Btu/h. This rate of mechanical work would then be subtracted from M to determine the net heat generated.

Heat Transfer Coefficients

Values for the linearized radiative heat transfer coefficient, convective heat transfer coefficient, and evaporative heat transfer coefficient are required to solve the equations describing heat transfer from the body.

Radiative heat transfer coefficient. The linearized radiative heat transfer coefficient can be calculated by:

$$h_r = 4\,\epsilon\,\sigma\,(A_r/A_D)\,[459.7 + (t_{cl} + \bar{t}_r)/2]^3 \qquad (50)$$

where

ϵ = average emissivity of clothing or body surface, dimensionless
σ = Stefan-Boltzmann constant, 0.1714 × 10⁻⁸ Btu/(h·ft²·°R⁴)
A_r = effective radiation area of body, ft²

The ratio A_r/A_D is 0.70 for a sitting person and 0.73 for a standing person (Fanger 1967). The emissivity is close to unity (typically 0.95), unless special reflective materials are used or high-temperature sources are involved. It is not always possible to solve Equation (50) explicitly for h_r, since t_{cl} may also be an unknown. Some form of iteration may be required if a precise solution is required. Fortunately, h_r is nearly constant for typical indoor temperatures, and a value of 0.83 Btu/(h·ft²·°F) suffices for most calculations. If the emissivity is significantly less than unity, the value should be adjusted by:

$$h_r = 0.83\,\epsilon \text{ Btu/(h·ft}^2\text{·°F)} \quad (51)$$

where ϵ represents the area-weighted average emissivity for the clothing/body surface.

Convective heat transfer coefficient. Heat transfer by convection is usually caused by air movement within the living space or by body movements. Equations for estimating h_c under various conditions are presented in Table 6. An additional relationship is presented in Equation (75). Where two conditions apply (*e.g.*, walking in moving air), a reasonable estimate can be obtained by taking the larger of the two values for h_c. Limits have been given to all equations. If no limits were given in the source, reasonable limits have been estimated. Care should be exercised in using these values for seated and reclining persons. The heat transfer coefficients may be accurate, but the effective heat transfer area may be substantially reduced due to body contact with a padded chair or bed.

Quantitative values of h_c are important, not only in estimating convection loss, but in evaluating (1) operative temperature t_o, (2) clothing parameters I_t and i_m, and (3) rational effective temperatures t_{oh} and ET*. All heat transfer coefficients in Table 6 were evaluated at or near 14.7 psia. These coefficients should be corrected as follows for atmospheric pressure:

$$h_{cc} = h_c(p_t/14.7)^{0.55} \quad (52)$$

where

h_{cc} = corrected convective heat transfer coefficient, Btu/(h·ft²·°F)
p_t = local atmospheric pressure, psia

The combined coefficient h is the sum of h_r and h_c described in Equation (50) and Table 6, respectively. The coefficient h governs exchange by radiation and convection from the exposed body surface to the surrounding environment.

Evaporative heat transfer coefficient. The evaporative heat transfer coefficient h_e for the outer air layer of a nude or clothed person can be estimated from the convective heat transfer coefficient using the Lewis relationship given in Equation (27). If the atmospheric pressure is significantly different from standard (14.7 psia), the correction to the value obtained from Equation (27) is:

$$h_{ec} = h_e\,(14.7/p_t)^{0.45} \quad (53)$$

Table 6 Equations for Convection Heat Transfer Coefficients

Equation	Limits	Condition	Remarks/Sources
$h_c = 0.061\,V^{0.6}$ $h_c = 0.55$	$40<V<800$ $0<V<40$	Seated with moving air	Mitchell (1974)
$h_c = 0.475 + 0.044\,V^{0.67}$ $h_c = 0.90$	$30<V<300$ $0<V<30$	Reclining with moving air	Colin and Houdas (1967)
$h_c = 0.092\,V^{0.53}$	$100<V<400$	Walking in still air	V is walking speed (Nishi and Gagge 1970)
$h_c = (M - 0.85)^{0.39}$	$1.1<M<3.0$	Active in still air	Gagge *et al.* (1976)
$h_c = 0.146\,V^{0.39}$	$100<V<400$	Walking on treadmill in still air	V is treadmill speed (Nishi and Gagge 1970)
$h_c = 0.068\,V^{0.69}$ $h_c = 0.70$	$30<V<300$ $0<V<30$	Standing person in moving air	Developed from data presented by Seppenan *et al.* (1972)

Note: h_c in Btu/(h·ft²·°F), V in fpm, and M in met units, where 1 met = 18.43 Btu/h·ft².

where h_{ec} is the corrected evaporative heat transfer coefficient, Btu/(h·ft²·°F).

Clothing Insulation and Moisture Permeability

Thermal insulation. The most accurate methods for determining clothing insulation are: (1) measurements on heated manikins (McCullough and Jones 1984, Olesen and Nielsen 1983) and (2) measurements on active subjects (Nishi *et al.* 1975). For most routine engineering work, estimates based on tables and equations presented in this section are sufficient. Thermal manikins can measure the sensible heat loss from the "skin" $(C + R)$ in a given environment. Equation (12) can then be used to evaluate R_{cl} if the environmental conditions are well defined and f_{cl} is measured. Evaluation of clothing insulation on subjects requires measurement of t_{sk}, t_{cl}, and t_o. The clothing thermal efficiency is calculated by:

$$F_{cl} = (t_{cl} - t_o)/(t_{sk} - t_o) \quad (54)$$

The intrinsic clothing insulation can then be calculated from manikin measurements by the following relationship, provided f_{cl} is measured and conditions are sufficiently well-defined to make an accurate determination of h:

$$R_{cl} = (t_{sk} - t_o)/q - 1/(hf_{cl}) \quad (55)$$

where q = heat loss from the manikin, Btu/(h·ft²).

Traditionally, clothing insulation value is expressed in clo units. In order to avoid confusion, the symbol I is used with the clo unit instead of the symbol R. The relationship between the two is:

Table 7 Typical Insulation and Permeability Values for Clothing Ensembles[a]

Ensemble Description[b]	I_{cl} (clo)	I_t[c] (clo)	f_{cl}	i_{cl}	i_m[c]
Walking shorts, short-sleeve shirt	0.36	1.02	1.10	0.34	0.42
Trousers, short-sleeve shirt	0.57	1.20	1.15	0.36	0.43

Same as above, plus suit jacket	0.96	1.54	1.23		
Same as above, plus vest and t-shirt	1.14	1.69	1.32	0.32	0.37
Trousers, long-sleeve shirt, long-sleeve sweater, t-shirt	1.01	1.56	1.28		
Same as above, plus suit jacket and long underwear bottoms	1.30	1.83	1.33		
Sweat pants, sweat shirt	0.74	1.35	1.19	0.41	0.45
Long-sleeve pajama top, long pajama trousers, short 3/4 sleeve robe, slippers (no socks)	0.96	1.50	1.32	0.37	0.41
Knee-length skirt, short-sleeve shirt, panty hose, sandals	0.54	1.10	1.26		
Knee-length skirt, long-sleeve shirt, full slip, panty hose	0.67	1.22	1.29		
Knee-length skirt, long-sleeve shirt, half slip, panty hose, long-sleeve sweater	1.10	1.59	1.46		
Same as above, replace sweater with suit jacket	1.04	1.60	1.30	0.35	0.40
Ankle-length skirt, long-sleeve shirt, suit jacket, panty hose	1.10	1.59	1.46		
Long-sleeve coveralls, t-shirt	0.72	1.30	1.23		
Overalls, long-sleeve shirt, t-shirt	0.89	1.46	1.27	0.35	0.40
Insulated coveralls, long-sleeve thermal underwear, long underwear bottoms	1.37	1.94	1.26	0.35	0.39

[a] From McCullough and Jones (1984) and McCullough *et al.* (1989)
[b] All ensembles include shoes and briefs or panties. All ensembles except those with panty hose include socks unless otherwise noted.
[c] For $\bar{t}_r = t_a$ and air velocity less than 40 ft/min (I_a = 0.72 clo and i_m = 0.48 when nude)

$$R = 0.88\,I \tag{56}$$

or 1.0 clo is equivalent to 0.88 ft²·h·°F/Btu.

Since clothing insulation cannot be measured for most routine engineering applications, tables of measured values for various clothing ensembles can be used to select an ensemble comparable to the one(s) in question. Table 7 gives values for typical indoor clothing ensembles. More detailed tables are presented by McCullough and Jones (1984) and Olesen and Nielsen (1983). Accuracies for I_{cl} on the order of ±20% are typical if good matches between ensembles are found.

Often it is not possible to find an already measured clothing ensemble that matches the one in question. In this case, the ensemble insulation can be estimated from the insulation of individual garments. Table 8 gives a list of individual garments commonly worn. The insulation of an ensemble is estimated from the individual values using a summation formula (McCullough and Jones 1984):

$$I_{cl} = 0.835 \sum_i I_{clu,i} + 0.161 \tag{57}$$

where $I_{clu,i}$ is the effective insulation of garment i, and I_{cl}, as before, is the insulation for the entire ensemble. A simpler and nearly as accurate summation formula is (Olesen 1985):

$$I_{cl} = \sum_i I_{clu,i} \tag{58}$$

Either Equation (57) or (58) gives acceptable accuracy for typical indoor clothing. The main source of inaccuracy is in determining the appropriate values for individual garments. Overall accuracies are on the order of ±25% if the tables are used carefully. If it is important to include a specific garment that is not included in Table 8, its insulation can be estimated by (McCullough and Jones 1984):

$$I_{clu,i} = (0.534 + 3.43\,x_f)\,(A_G/A_D) - 0.0549 \tag{59}$$

where

x_f = fabric thickness, in.
A_G = body surface area covered by garment, ft²

Values in Table 7 may be adjusted by information in Table 8 and a summation formula. Using this method, values of $I_{clu,i}$ for the selected items in Table 8 are then added to or subtracted from the ensemble value of I_{cl} in Table 7.

Moisture permeability. Moisture permeability data for some clothing ensembles are presented in terms of i_{cl} and i_m in Table 7. The values of i_m can be used to calculate $R_{e,t}$ using the relationships in Table 2. Ensembles worn indoors generally fall in the range $0.3 < i_m < 0.5$ and assuming $i_m = 0.4$ is reasonably accurate (McCullough *et al.* 1989). This latter value may be used if a good match to ensembles in Table 7 cannot be made. The value of i_m or $R_{e,t}$ may be substituted directly into equations for body heat loss calculations (see Table 3). However, i_m for a given clothing ensemble is a function of the environment as well as the clothing properties. Unless i_m is evaluated at conditions very similar to the intended application, it is more rigorous to use i_{cl} to describe the moisture permeability of the clothing. The value of i_{cl} is not as sensitive to environmental conditions; thus, given data are more accurate over a wider range of air velocity and radiant and air temperature combinations for i_{cl} than for i_m. The relationships in Table 2 can be used to determine $R_{e,cl}$ from i_{cl}, and i_{cl} or $R_{e,cl}$ can then be used for body heat loss calculations (see Table 3). McCullough *et al.* (1989) found an average value of $i_{cl} = 0.34$ for common indoor clothing; this value can be used when other data are not available.

Measurements of i_m or i_{cl} may be necessary if unusual clothing (*e.g.*, impermeable or metalized) and/or extreme environments (*e.g.*, high radiant temperatures or high air velocities) are to be addressed. There are three different methods for measuring the moisture permeability of clothing: the first uses a wet manikin to measure the effect of sweat evaporation on heat loss (McCullough 1986); the second uses moisture permeability measurements on component fabrics as well as dry manikin measurements (Umbach 1980); the third uses measurements from sweating subjects (Nishi *et al.* 1975, Holmer 1984).

Table 8 Garment Insulation Values

Garment Description[a]	$I_{clu,i}$, clo[b]	Garment Description[a]	$I_{clu,i}$, clo[b]	Garment Description[a]	$I_{clu,i}$, clo[b]
Underwear		Short-sleeve, knit sport shirt	0.17	Sleeveless vest (thick)	0.22

Long-sleeve, flannel shirt	0.34	Sleeveless vest (thin)	0.13	Short-sleeve, short robe (thin)	0.34

[a] "Thin" garments are made of light, thin fabrics worn in the summer; "thick" garments are made of heavy, thick fabrics worn in the winter.

[b] 1 clo = 0.880°F·ft²·h/Btu

[c] Knee-length

Clothing surface area. Many clothing heat transfer calculations require the clothing area factor f_{cl} to be known. The most reliable approach is to measure it using photographic methods (Olesen *et al.* 1982). Other than actual measurements, the best method is to use previously tabulated data for similar clothing ensembles. Table 7 is adequate for most indoor clothing ensembles. No good method of estimating f_{cl} for a clothing ensemble from other information is available, although a rough estimate can be made by (McCullough and Jones 1984):

$$f_{cl} = 1.0 + 0.3\, I_{cl} \tag{60}$$

Total Evaporative Heat Loss

The total evaporative heat loss (latent heat) from the human body due to both respirative losses and skin losses, $E_{sk} + E_{res}$, can be measured directly from the body's rate of mass loss as observed by a sensitive scale:

$$E_{sk} + E_{res} = h_{fg}\,(dm/d\theta)/A_D \tag{61}$$

where

h_{fg} = latent heat of vaporization of water, Btu/lb
m = body mass, lb
θ = time, h

When using Equation (61), adjustments should be made for any materials consumed (*e.g.*, food and drink) and body effluents (*e.g.*, wastes). The fuel burned by the body also contributes slightly to weight loss and can be accounted for with the following relationship (Astrand and Rodahl 1977):

$$dm_{gc}/d\theta = 2.2 V_{O_2}(0.1225\ \mathrm{RQ} - 0.0891) \tag{62}$$

where

$dm_{gc}/d\theta$ = mass loss due to respiratory gas exchange, lb/h
V_{O_2} = O_2 uptake at STPD, ft^3/h
RQ = respiratory quotient
0.1225 = density of CO_2 at STPD, lb/ft^3
0.0891 = density of O_2 STPD, lb/ft^3
STPD = standard temperature and pressure dry, 32°F, 14.7 psia

Environmental Parameters

The parameters describing the thermal environment that must be measured or otherwise quantified if accurate estimates of human thermal response are to be made are divided into two groups—those that can be measured directly and those that are calculated from other measurements.

Directly measured. Seven of the parameters frequently used to describe the thermal environment are psychrometric and include (1) air temperature t_a; (2) wet-bulb temperature t_{wb}; (3) dew-point temperature t_{dp}; (4) water vapor pressure p_a; (5) total atmospheric pressure p_t; (6) relative humidity (rh); and (7) humidity ratio W. These parameters are discussed in detail in Chapter 6, and methods for measuring them are discussed in Chapter 13. Two other important parameters that can be measured directly include air velocity V and mean radiant temperature $\bar{t}_r$. Air velocity measurements are also discussed in Chapter 13. The radiant temperature is the temperature of an exposed surface in the environment. The temperatures of individual surfaces are usually combined into a mean radiant temperature $\bar{t}_r$. Finally, globe temperature t_g, which can also be measured directly, is a good approximation of the operative temperature t_o and is also used with other measurements to calculate the mean radiant temperature (see Chapter 13).

Calculated parameters. The *mean radiant temperature* $\bar{t}_r$ is a key variable in making thermal calculations for the human body. It is the uniform temperature of an imaginary enclosure in which radiant heat transfer from the human body equals the radiant heat transfer in the actual nonuniform enclosure. Measurements of the globe temperature, air temperature, and the air velocity can be combined to estimate the mean radiant temperature (see Chapter 13). The accuracy of the mean radiant temperature determined this way varies considerably depending on the type of environment and the accuracy of the individual measurements. Since the mean radiant temperature is defined with respect to the human body, the shape of the sensor is also a factor. The spherical shape of the globe thermometer gives a reasonable approximation for a seated person; an ellipsoid-shaped sensor gives a better approximation to the shape of a human, both upright and seated.

The mean radiant temperature can also be calculated from measured values of the temperature of the surrounding walls and surfaces and their positions with respect to the person. As most building materials have a high emittance ϵ, all the surfaces in the room can be assumed to be black. The following equation is then used:

$$\bar{T}_r^4 = T_1^4 F_{p-1} + T_2^4 F_{p-2} + \ldots + T_N^4 F_{p-N} \tag{63}$$

where

$\bar{T}_r$ = mean radiant temperature, °R
T_N = surface temperature of surface N, °R
F_{p-N} = angle factor between a person and surface N

As the sum of the angle factors is unity, the fourth power of mean radiant temperature equals the mean value of the surrounding surface temperatures to the fourth power, weighted by the respective angle factors. In general, angle factors are difficult to determine, although Figures 3a and 3b may be used to estimate them for rectangular surfaces. The angle factor normally depends on the position and orientation of the person (Fanger 1982).

If relatively small temperature differences exist between the surfaces of the enclosure, Equation (63) can be simplified to a linear form:

$$\bar{t}_r = t_1 F_{p-1} + t_2 F_{p-2} + \ldots + t_N F_{p-N} \tag{64}$$

Equation (64) always gives a slightly lower mean radiant temperature than Equation (63), but in many cases the difference is small. If, for example, half the surroundings ($F_{p-N} = 0.5$) has a temperature 10°F higher than the other half, the difference between the calculated mean radiant temperatures—according to Equations (63) and (64)—is only 0.4°F. If, however, this difference is 200°F, the mean radiant temperature calculated by Equation (64) is 20°F too low.

The mean radiant temperature may also be calculated from the plane radiant temperature t_{pr} (defined later) in six directions (up, down, left, right, front, back) and for the projected area factors of a person in the same six directions. For a standing person, the mean radiant temperature may be estimated as:

$$\bar{t}_r = \{0.08\,[t_{pr}(\mathrm{up}) + t_{pr}(\mathrm{down})] + 0.23\,[t_{pr}(\mathrm{right}) + t_{pr}(\mathrm{left})] + 0.35\,[t_{pr}(\mathrm{front}) + t_{pr}(\mathrm{back})]\} / [2\,(0.08 + 0.23 + 0.35)] \tag{65}$$

For a seated person, the mean radiant temperature may be estimated as:

$$\bar{t}_r = \{0.18\,[t_{pr}(\mathrm{up}) + t_{pr}(\mathrm{down})] + 0.22\,[t_{pr}(\mathrm{right}) + t_{pr}(\mathrm{left})] + 0.30\,[t_{pr}(\mathrm{front}) + t_{pr}(\mathrm{back})]\} / [2\,(0.18 + 0.22 + 0.30)] \tag{66}$$

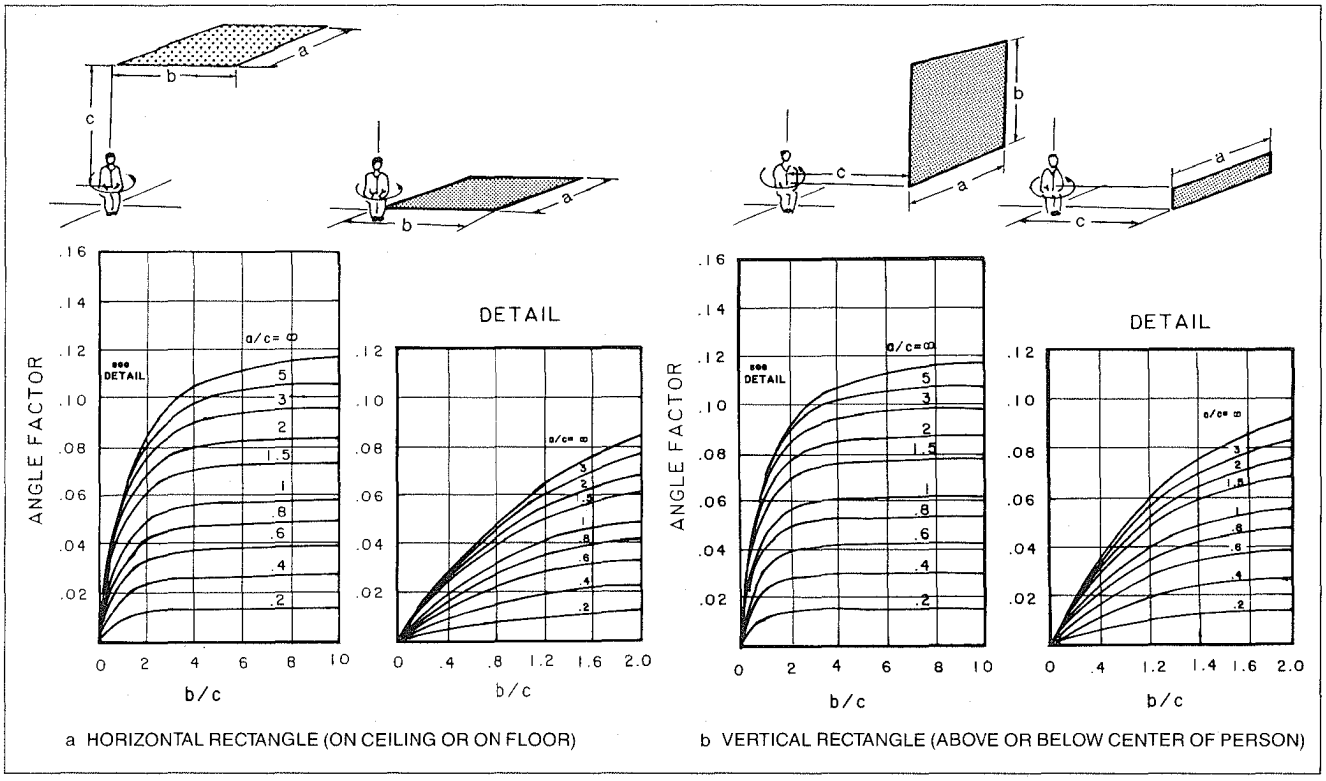

Fig. 3 Mean Value of Angle Factor between Seated Person and Horizontal or Vertical Rectangle when Person is Rotated around Vertical Axis
(Fanger 1982)

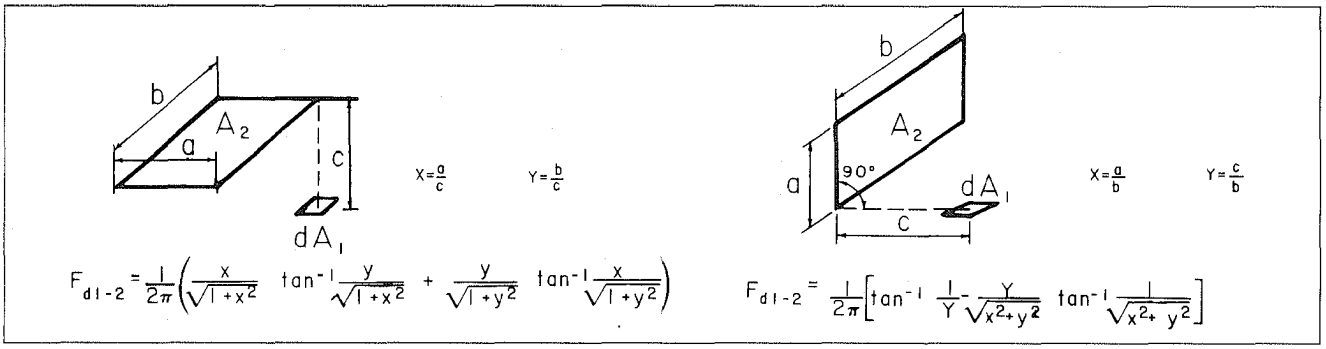

Fig. 3c Analytical Formulae for Calculating Angle Factor for Small Plane Element

The *plane radiant temperature* t_{pr}, first introduced by McIntyre (1974), is the uniform temperature of an enclosure in which the incident radiant flux on one side of a small plane element is the same as that in the actual environment. The plane radiant temperature describes the thermal radiation in one direction and its value thus depends on the direction. In comparison, the mean radiant temperature describes the thermal radiation for the human body from all directions. The plane radiant temperature can be calculated using Equations (63) and (64) with the same limitations. Area factors are determined from Figure 3c.

The *radiant temperature asymmetry* Δt_{pr} is the difference between the plane radiant temperature of the opposite sides of a small plane element. This parameter describes the asymmetry of the radiant environment, and is especially important in comfort conditions. Because it is defined with respect to a plane element, its value depends on the orientation of that plane. This orientation may be specified in some situations (*e.g.*, floor to ceiling asymmetry) and not in others. If direction is not specified, the radiant asymmetry should be for the orientation that gives the maximum value.

ENVIRONMENTAL INDICES

A number of indices simplify the description of the thermal environment and the stress imposed by an environment. An environmental index combines two or more parameters, such as air temperature, mean radiant temperature, humidity, or air velocity, into a single variable. Environmental indices may be classified according to how they are developed. Rational indices are based on the theoretical concepts presented earlier. Empirical indices are based on measurements with subjects or on simplified relationships that do not necessarily follow theory. Indices may also be classified according to their application, generally either heat stress or cold stress.

Effective Temperature

The *effective temperature* ET* is probably the most common environmental index and has the widest range of application. It combines temperature and humidity into a single index, so two environments with the same ET* should evoke the same thermal response even though they have different temperatures and humidities; but they must have the same air velocities. The original empirical effective temperature was developed by Houghton and Yaglou (1923). Gagge *et al.* (1971) defined a new effective temperature using a rational approach. Defined mathematically in Equation (33), this is the temperature of an environment at 50% rh that results in the same total heat loss from the skin E_{sk} as in the actual environment. Since the index is defined in terms of operative temperature t_o, it combines the effect of three parameters—$\bar{t}_r$, t_a, and p_a—into a single index. Skin wettedness w and the permeability index i_m must be specified and are constant for a given ET* line for a particular situation. The two-node model is used to determine skin wettedness in the zone of evaporative regulation. At the upper limit of regulation, w approaches 1.0, and at the lower limit, w approaches 0.06; skin wettedness equals one of these values when the body is outside the zone of evaporative regulation. Since the slope of a constant ET* line depends on skin wettedness and clothing moisture permeability, effective temperature for a given temperature and humidity may depend on the clothing of the person and their activity. This difference is shown in Figure 4. At low skin wettedness, the air humidity has little influence, and lines of constant ET* are nearly vertical. As skin wettedness increases due to activity and/or heat stress, the lines become more horizontal and the influence of humidity is much more pronounced. The ASHRAE comfort envelope shown in Figure 5 is described in terms of ET*.

Since ET* depends on clothing and activity, it is not possible to generate a universal ET* chart. Calculation of ET* can also be tedious, requiring the solution of multiple coupled equations to determine skin wettedness. These equations can be solved with the appropriate computer routines (Gagge *et al.* 1971), but not always with hand calculations. A standard set of conditions representative of typical indoor applications is used to define a *standard effective temperature* (SET*). The standard effective temperature is then defined as the equivalent air temperature of an isothermal environment at 50% rh in which a subject, while wearing clothing standardized for the activity concerned, has the same heat stress (skin temperature t_{sk}) and thermoregulatory strain (skin wettedness w) as in the actual environment.

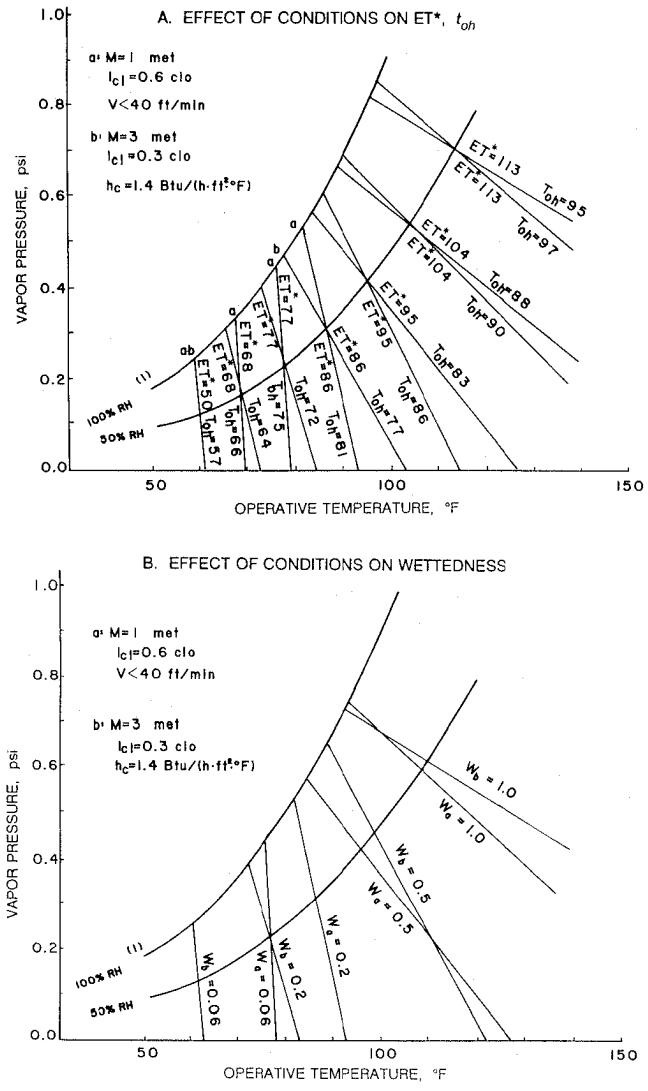

Fig. 4 Effective Temperature (ET*) and Skin Wettedness (W)
(Adapted from Nishi *et al.* 1975 and Gonzalez *et al.* 1978)

Humid Operative Temperature

The *humid operative temperature* t_{oh} is the temperature of a uniform environment at 100% rh in which a person loses the same total amount of heat from the skin as in the actual environment. This index is defined mathematically in Equation (32). It is analogous to ET*, the only difference being that it is defined at 100% rh and 0% rh rather than at 50% rh. Figures 2 and 4 indicate that lines of constant ET* are also lines of constant t_{oh}. However, the values of these two indices differ for a given environment.

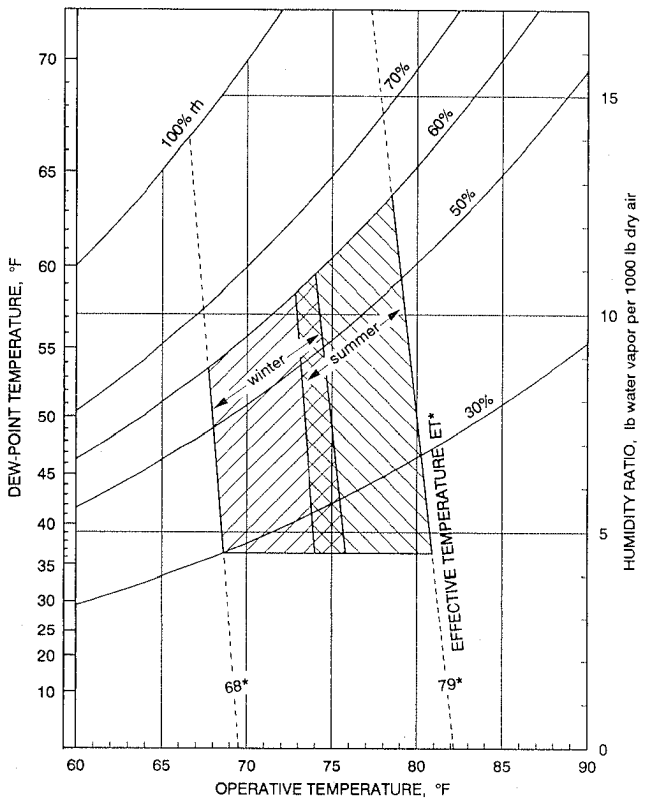

Fig. 5 Standard Effective Temperature and ASHRAE Comfort Zones

Heat Stress Index

Originally proposed by Belding and Hatch (1955), this rational index is the ratio of the total evaporative heat loss E_{sk} required for thermal equilibrium (the sum of metabolism plus dry heat load) to the maximum evaporative heat loss E_{max} possible for the environment, multiplied by 100, for steady-state conditions (S_{sk} and S_{cr} are zero), and with t_{sk} held constant at 95 °F. The ratio E_{sk}/E_{max} equals skin wettedness as is shown in Equation (19). When HSI > 100, body heating occurs; when HSI < 0, body cooling occurs. Belding and Hatch (1955) limited E_{max} to 220 Btu/(h·ft²), which corresponds to a sweat rate of approximately 0.21 lb/(h·ft²). When t_{sk} is constant, loci of constant HSI coincide with lines of constant ET* on a psychrometric chart. Other indices based on wettedness of the original HSI concept have the same practical applications (Gonzalez *et al.* 1978, Belding 1970, ISO *Standard* 7933), but differ in their treatment of E_{max} and the effect of clothing. Table 9 describes physiological factors associated with HSI values.

Index of Skin Wettedness

This index is the ratio of observed skin sweating E_{sk} to the E_{max} of the environment as defined by t_{sk}, t_a, humidity, air movement, and clothing in Equation (13). Except for the factor of 100, it is essentially the same as the heat stress index. Skin wettedness is more closely related to the sense of discomfort or unpleasantness than to temperature sensation (Gagge *et al.* 1969a, 1969b; Gonzalez *et al.* 1978).

Wet-Bulb Globe Temperature

The WBGT is an environmental heat stress index that combines dry-bulb temperature t_{db}, a *naturally ventilated* (not aspirated) wet-bulb temperature t_{nwb}, and black globe temperature t_g, according to the relation (Dukes-Dobos and Henschel 1971, 1973):

$$\text{WBGT} = 0.7\,t_{nwb} + 0.2\,t_g + 0.1\,t_a \qquad (67)$$

Table 9 Evaluation of Heat Stress Index

Heat Stress Index	Physiological and Hygienic Implications of 8-h Exposures to Various Heat Stresses
0	No thermal strain.
10 20 30	Mild to moderate heat strain. If job involves higher intellectual functions, dexterity, or alertness, subtle to substantial decrements in performance may be expected. In performing heavy physical work, little decrement is expected, unless ability of individuals to perform such work under no thermal stress is marginal.
40 50 60	Severe heat strain involving a threat to health unless men are physically fit. Break-in period required for men not previously acclimatized. Some decrement in performance of physical work is to be expected. Medical selection of personnel desirable, because these conditions are unsuitable for those with cardiovascular or respiratory impairment or with chronic dermatitis. These working conditions are also unsuitable for activities requiring sustained mental effort.
70 80 90	Very severe heat strain. Only a small percentage of the population may be expected to qualify for this work. Personnel should be selected: (a) by medical examination, and (b) by trial on the job (after acclimatization). Special measures are needed to assure adequate water and salt intake. Amelioration of working conditions by any feasible means is highly desirable, and may be expected to decrease the health hazard while increasing job efficiency. Slight "indisposition", which in most jobs would be insufficient to affect performance, may render workers unfit for this exposure.
100	The maximum strain tolerated daily by fit, acclimatized young men.

This form of the equation is usually used where solar radiation is present. The naturally ventilated wet-bulb thermometer is left exposed to the sunlight, but the air temperature t_a sensor is shaded. In enclosed environments, Equation (67) is simplified by dropping the t_a term and using a 0.3 weighting factor for t_g.

The black globe thermometer is responsive to air temperature, mean radiant temperature, and air movement, while the naturally ventilated wet-bulb thermometer responds to air humidity, air movement, radiant temperature, and air temperature. Thus, WBGT is a function of all four environmental factors affecting human environmental heat stress.

The WBGT is a better index of heat stress than the old ET; it shows almost as good a correlation with sweat rate as do the later Corrected Effective Temperature (CET) and the Effective Temperature with Radiation (ETR) indices (Minard 1961); the CET and ETR both require direct measurement of wind velocity which, for accuracy, requires special instruments and trained technicians.

The WBGT index is widely used for estimating the heat stress potential of industrial environments (Davis 1976). In the United States, the National Institute of Occupational Safety and Health (NIOSH) developed a criteria document for a heat-stress limiting standard (NIOSH 1986). ISO *Standard* 7243 (ISO 1982) also uses the WBGT. Figure 6 is a graphical summary of the permissible heat exposure limits, expressed as working time per hour, for a fit individual, as specified for various WBGT levels. Values apply for normal permeable clothing (0.6 clo) and must be adjusted for heavy or partly vapor-permeable clothing. USAF (1980) recommends adjusting the measured WBGT upwards by 10 °F for personnel wearing chemical protective clothing or body armor. This type of clothing increases the resistance to sweat evaporation about threefold (higher if it is totally impermeable), requiring an adjustment in WBGT level to compensate for reduced evaporative cooling at the skin.

Several mathematical models are available for predicting WBGT from the environmental factors: air temperature, psychrometric wet-bulb temperature, mean radiant temperature, and air motion (Azer and Hsu 1977, Sullivan and Gorton 1976). A simpler approach, involving plotting WBGT lines on a psychromet-

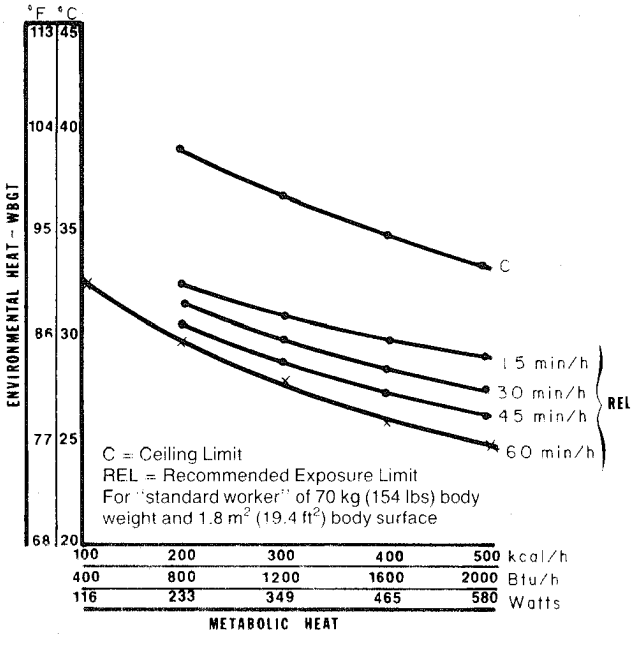

Fig. 6 Recommended Heat Stress Exposure Limits for Heat Acclimatized Workers
(From United States DHHS (NIOSH) Publication 86-113, 1986)

ric chart, is recommended. Isotherms of WBGT are parallel and have negative slopes varying from 0.014 psi/°F for still air to 0.016 psi/°F for air motion greater than 200 fpm. By comparison, psychrometric wet-bulb lines have negative slopes of about 0.0056 psi/°F, or are about 35% as steep.

Wet-Globe Temperature

The WGT, introduced by Botsford (1971), is a simpler approach to measuring environmental heat stress than the WBGT. The measurement is made with a wetted globe thermometer called a Botsball, which consists of a 2.5 in. black copper sphere covered with a fitted wet black mesh fabric, into which the sensor of a dial thermometer is inserted. A polished stem attached to the sphere supports the thermometer and contains a water reservoir for keeping the sphere covering wet. This instrument is suspended by the stem at the indoor (or outdoor) site to be measured.

Onkaram (1980) has shown that WBGT can be predicted with reasonable accuracy from WGT for temperate to warm environments with medium to high humidities. With air temperatures between 68 and 95 °F, dew points ranging from 45 to 77 °F (relative humidities above 30%), and wind speeds of 15 mph or less, the experimental regression equation ($r = 0.98$) in °F for an outdoor environment is:

$$\text{WBGT} = 1.044\,\text{WGT} - 1.745 \qquad (68)$$

This equation should not be used outside the experimental range just given, since data from hot-dry desert environments show differences between WBGT and WGT that are too large (10 °F and above) to be adjusted by Equation (68) (Matthew 1986). With very low humidity combined with high wind, WGT approaches the psychrometric wet-bulb temperature, which is greatly depressed below t_a. However, in the WBGT, t_{nwb} accounts for only 70% of the index value, with the remaining 30% at or above t_a.

Ciriello and Snook (1977) handle the problem by providing a series of regression equations, the choice depending on the levels of wind speed, humidity, and radiant heat. They report an accuracy of conversion from WGT to WBGT within 0.7 °F (90% confidence level), if good estimates of wind speed, humidity, and radiation level are available.

Wind Chill Index

The wind chill index (WCI) is an empirical index developed from cooling measurements obtained in Antarctica on a cylindrical flask partly filled with water (Siple and Passel 1945). The index describes the rate of heat loss from the cylinder by radiation and convection for a surface temperature of 91.4 °F, as a function of ambient temperature and wind velocity. As originally proposed:

$$\text{WCI} = (10.45 - 0.447\,V + 6.686\sqrt{V})\,(91.4 - t_a)/1.8 \qquad (69)$$

where V and t_a are in mph and °F, respectively. The 91.4 °F surface temperature was chosen to be representative of the mean skin temperature of a resting human in comfortable surroundings.

A number of valid objections have been raised about this formulation. Cooling rate data from which it was derived were measured on a 2.24 in. diameter plastic cylinder, making it unlikely that WCI would be an accurate measure of heat loss from exposed flesh, which has different characteristics than the plastic (curvature, roughness, and radiation exchange properties) and is invariably below 91.4 °F in a cold environment. Moreover, values given by the equation peak at 56 mph, then decrease with increasing velocity.

Nevertheless, for velocities below 50 mph, this index reliably expresses combined effects of temperature and wind on subjective discomfort. For example, if the calculated WCI is less than 1400 and actual air temperature is above 14 °F, there is little risk of frostbite during brief exposures (1 h or less), even for bare skin. However, at a WCI of 2000 or more, the probability is high that exposed flesh will begin to freeze in 1 min or less unless preventive measures are taken to shield the exposed skin (such as a fur ruff to break up the wind around the face).

Rather than using the WCI to express the severity of a cold environment, meteorologists use an index derived from the WCI called the *equivalent wind chill temperature.* This is the ambient temperature that would produce, in a calm wind (defined for this application as 4 mph), the same WCI as the actual combination of air temperature and wind velocity. Equivalent wind chill temperature $t_{eq,wc}$ in °F can be calculated by:

$$t_{eq,wc} = -0.0818\,(\text{WCI}) + 91.4 \qquad (70)$$

where $t_{eq,wc}$ is expressed as a temperature (and frequently referred to as a wind chill factor), thus distinguishing it from WCI, which is given either as a cooling rate or as a plain number with no units. For velocities less than 4 mph, Equation (70) does not apply, and the wind chill temperature is equal to the air temperature.

Equation (70) does not imply cooling to below ambient temperature, but recognizes that, because of wind, the cooling rate is increased as though it were occurring at the lower equivalent wind chill temperature. Wind accelerates the rate of heat loss, so that

Table 10 Equivalent Wind Chill Temperatures of Cold Environments[a]

Wind Speed, mph	Actual Thermometer Reading, °F											
	50	40	30	20	10	0	−10	−20	−30	−40	−50	−60
	Equivalent Chill Temperature, °F											
0	50	40	30	20	10	0	−10	−20	−30	−40	−50	−60
5	48	37	27	16	6	−5	−15	−26	−36	−47	−57	−68
10	40	28	16	3	−9	−21	−34	−46	−58	−71	−83	−95
15	36	22	9	−5	−18	−32	−45	−59	−72	−86	−99	−113
20	32	18	4	−11	−25	−39	−53	−68	−82	−96	−110	−125
25	30	15	0	−15	−30	−44	−59	−74	−89	−104	−119	−134
30	28	13	−3	−18	−33	−48	−64	−79	−94	−110	−125	−140
35	27	11	−4	−20	−36	−51	−67	−83	−98	−114	−129	−145
40	26	10	−6	−22	−38	−53	−69	−85	−101	−117	−133	−148
	Little danger: In less than 5 h, with dry skin. Maximum danger from false sense of security. (WCI less than 1400)				**Increasing danger:** Danger of freezing exposed flesh within one minute. (WCI between 1400 and 2000)			**Great danger:** Flesh may freeze within 30 seconds. (WCI greater than 2000)

the skin surface is cooling faster toward the ambient temperature. Table 10 shows a typical wind chill chart, expressed in equivalent wind chill temperature.

PREDICTION OF THERMAL COMFORT AND THERMAL SENSATION

Thermal comfort is defined as "that condition of mind in which satisfaction is expressed with the thermal environment." Because comfort is a "condition of mind," empirical equations must be used to relate comfort perceptions to specific physiological responses. In addition to the previously discussed independent environmental and personal variables influencing thermal response and comfort, other factors such as nonuniformity of the environment, visual stimuli, age, outdoor climate, etc. may also have some effect, but are generally considered to be secondary factors.

Conditions for Thermal Comfort

Studies by Rohles and Nevins (1971) and Rohles (1973) on 1600 college-age students revealed statistical correlations between comfort level, temperature, humidity, sex, and length of exposure. The equations from this study for predicting thermal sensations from air temperature and atmospheric water vapor pressure for men and women for different exposure periods are shown in Table 11. The thermal sensation scale used in these equations is referred to as the ASHRAE thermal sensation scale and is the same as the PMV scale described later. This scale is as follows:

+3 hot
+2 warm
+1 slightly warm
0 neutral
−1 slightly cool
−2 cool
−3 cold

Vapor pressure rather than conventional relative humidity was used in these equations. Plotting the regression equation results in sets of observed lines of *equal thermal sensation* for lightly clothed, sedentary young adults.

Design data given in the equations (Table 11) define conditions that maximize thermal acceptability of the environment for a large group of similarly clothed, active adults and minimize the fraction of expected complaints.

Steady-State Energy Balance

Fanger (1982) related the comfort data to physiological variables. At a given level of metabolic activity M, and when the body is not far from thermal neutrality, the mean skin temperature t_{sk} and sweat rate E_{rsw} are the only physiological parameters influencing the heat balance. However, heat balance alone is not sufficient to establish thermal comfort. In the wide range of environmental conditions where heat balance can be obtained, only a narrow range provides thermal comfort. The following linear regression equations based on Rohles' and Nevins' data indicate values of t_{sk} and E_{rsw} that provide thermal comfort.

$$t_{sk,req} = 96.3 - 0.156\,(M - W) \text{ in } °F \quad (71)$$

$$E_{rsw,req} = 0.42\,(M - W - 18.43) \text{ in Btu/(h·ft}^2\text{)} \quad (72)$$

The mean skin temperature decreases at higher activities and the sweat loss increases. Both reactions increase the heat loss from the body core to the environment. These two empirical relationships link the physiological and heat flow equations and thermal comfort perceptions. By substituting these values into Equation (12) for $(C + R)$, and into Equations (18) and (19) for E_{sk}, the energy balance Equation (1) can be used to determine combinations of the six environmental and personal parameters that optimize comfort for steady-state conditions.

Fanger (1982) reduced these relationships to a single equation, which assumed all sweat generated is evaporated, eliminating clothing moisture permeability as a factor in the equation. This assumption is valid for normal indoor clothing worn in typical indoor environments with low or moderate activity levels. At higher activity levels ($M_{act} > 3$ met), where a significant amount of sweating occurs even at optimum comfort conditions, this assumption may limit accuracy. The reduced equation is slightly different from the heat transfer equations developed here. The radiant heat exchange is expressed in terms of the Stefan-Boltzmann law (instead of using h_r), and diffusion of water vapor through the skin is expressed in terms of a diffusivity coefficient and a linear approximation for saturated vapor pressure evaluated at t_{sk}. The combination of environmental and personal variables that produce a neutral sensation may be expressed as follows:

$$\begin{aligned}(M - W) = {} & 1.196 \times 10^{-9} f_{cl}[(t_{cl} + 460)^4 - (\bar{t}_r + 460)^4] \\ & + f_{cl} h_c (t_{cl} - t_a) \\ & + 0.97\,[5.73 - 0.022\,(M - W) - 6.9\,p_a] \\ & + 0.42\,[(M - W) - 18.43] \\ & + 0.0173\,M\,(5.87 - 6.9\,p_a) \\ & + 0.00077\,M\,(93.2 - t_a)\end{aligned} \quad (73)$$

where

$$\begin{aligned}t_{cl} = {} & 96.3 - 0.156\,(M - W) \\ & - R_{cl}[(M - W) \\ & - 0.97\,[5.73 - 0.022\,(M - W) - 6.9\,p_a] \\ & - 0.42\,[(M - W) - 18.43] - 0.0173\,M(5.87 - 6.9\,p_a) \\ & - 0.00077\,M\,(93.2 - t_a)]\end{aligned} \quad (74)$$

The values of h_c and f_{cl} can be estimated from tables and equations given in the Engineering Data and Measurements section. Fanger used the following relationships:

$$h_c = \begin{cases} 0.361\,(t_{cl} - t_a)^{0.25} & 0.361\,(t_{cl} - t_a)^{0.25} > 0.151\sqrt{V} \\ 0.151\sqrt{V} & 0.361\,(t_{cl} - t_a)^{0.25} < 0.151\sqrt{V} \end{cases} \quad (75)$$

Table 11 Equations for Predicting Thermal Sensation (Y)[a] of Men, Women, and Men and Women Combined[b]

Exposure Period, h	Sex	Regression Equations (t = dry-bulb temperature, °F; p = vapor pressure, psi)
1.0	Male	$Y = 0.122\,t + 1.61\,p - 9.584$
	Female	$Y = 0.151\,t + 1.71\,p - 12.080$
	Combined	$Y = 0.136\,t + 1.71\,p - 10.880$
2.0	Male	$Y = 0.123\,t + 1.86\,p - 9.953$
	Female	$Y = 0.157\,t + 1.45\,p - 12.725$
	Combined	$Y = 0.140\,t + 1.65\,p - 11.339$
3.0	Male	$Y = 0.118\,t + 2.02\,p - 9.718$
	Female	$Y = 0.153\,t + 1.76\,p - 13.511$
	Combined	$Y = 0.135\,t + 1.92\,p - 11.122$

[a] Y values refer to the ASHRAE thermal sensation scale.
[b] For young adult subjects with sedentary activity and wearing clothing with a thermal resistance of approximately 0.5 clo, $\bar{t}_r \cong \bar{t}_a$ and air velocities are < 40 fpm.

$$f_{cl} = \begin{cases} 1.0 + 0.2\,I_{cl} & I_{cl} < 0.5 \text{ clo} \\ 1.05 + 0.1\,I_{cl} & I_{cl} > 0.5 \text{ clo} \end{cases} \quad (76)$$

Figures 7 and 8 show examples of how Equation (73) can be used.

Equation (73) is expanded to include a range of thermal sensations by using a *predicted mean vote* (PMV) index. The PMV index predicts the mean response of a large group of people according to the ASHRAE thermal sensation scale. Fanger (1970) related PMV to the imbalance between the actual heat flow from the body in a given environment and the heat flow required for optimum comfort at the specified activity by the following equation:

$$\text{PMV} = [0.303 \exp(-0.036\,M) + 0.028]\,L \quad (77)$$

where L is the thermal load on the body, defined as the difference between the internal heat production and the heat loss to the actual environment for a person hypothetically kept at comfort values of t_{sk} and E_{rsw} at the actual activity level. Thermal load L is then the difference between the left and right sides of Equation (73) when evaluated at the actual environmental conditions.

Two-Node Transient Energy Balance

After replacing the terms in Equations (2) and (3) with the expressions presented in the previous sections, the equations can be rearranged to calculate t_{sk} and t_{cr} at any time θ, using numerical integration for a specified time of exposure. At each time step, values for the individual energy flows and the thermoregulatory responses have to be recalculated since they are functions of t_{sk} and/or t_{cr}.

After calculating values of t_{sk}, t_{cr}, and w, the model uses empirical expressions to predict thermal sensation (TSENS) and thermal discomfort (DISC). These indices are based on 11-point numerical scales, where positive values represent the warm side of neutral sensation or comfort, and negative values represent the cool side. TSENS is based on the same scale as PMV, but with extra terms for ±4 (very hot/cold) and ±5 (intolerably hot/cold). Recognizing the same positive/negative convention for warm/cold discomfort, DISC is defined as:

5 intolerable
4 limited tolerance
3 very uncomfortable
2 uncomfortable and unpleasant
1 slightly uncomfortable but acceptable
0 comfortable

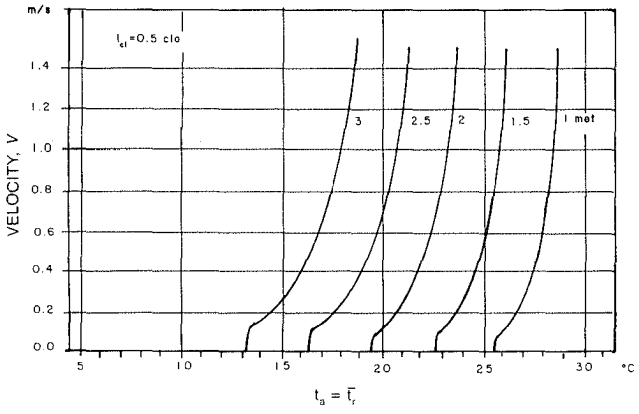

Fig. 7 Interaction between Air Velocity, Temperature, and Activity

TSENS is defined in terms of deviations of mean body temperature t_b from cold and hot set points representing the lower and upper limits for the zone of evaporative regulation: $t_{b,c}$ and $t_{b,h}$, respectively. The values of these set points depend on the net rate of internal heat production and are calculated by:

$$t_{b,c} = (0.194/58.15)\,(M - W) + 36.301 \quad (78)$$

$$t_{b,h} = (0.347/58.15)\,(M - W) + 36.669 \quad (79)$$

TSENS is then determined by:

$$\text{TSENS} = \begin{cases} 0.4685\,(t_b - t_{b,c}) & t_b < t_{b,c} \\ 4.7\,\eta_{ev}\,(t_b - t_{b,c})/(t_{b,h} - t_{b,c}) & t_{b,c} \leq t_b \leq t_{b,h} \\ 4.7\,\eta_{ev} + 0.4685\,(t_b - t_{b,h}) & t_{b,h} < t_b \end{cases} \quad (80)$$

where η_{ev} is the evaporative efficiency (assumed to be 0.85).

Thermal discomfort is numerically equal to TSENS when t_b is below its cold set point $t_{b,c}$ and is related to skin wettedness when body temperature is regulated by sweating:

$$\text{DISC} = \begin{cases} 0.4685\,(t_b - t_{b,c}) & t_b < t_{b,c} \\ \dfrac{4.7\,(E_{rsw} - E_{rsw,req})}{(E_{max} - E_{rsw,req} - E_{dif})} & t_{b,c} \leq t_b \end{cases} \quad (81)$$

where $E_{rsw,req}$ is calculated as in Fanger's model, using Equation (72).

Zones of Comfort and Discomfort

The preceding section shows that comfort and thermal sensation are not necessarily the same variable, especially for a person in the zone of evaporative thermal regulation. Figures 9 and 10 show this difference for the standard combination of met-clo-air movement used in the standard effective temperature. Figure 9 demonstrates that practically all basic physiological variables predicted by the two-node model are functions of ambient temperature and are relatively independent of vapor pressure. All exceptions occur at relative humidities above 80% and as the isotherms reach the ET* = 41.4°C line, where regulation by

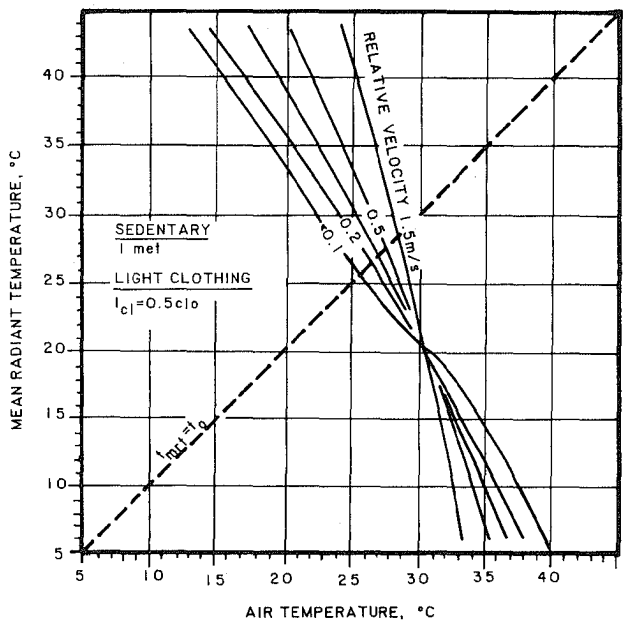

Fig. 8 Interaction between Air Temperature, Mean Radiant Temperature, and Velocity

evaporation fails. Figure 10 shows that lines of constant ET* and wettedness are functions of both ambient temperature and vapor pressure. Thus, human thermal responses are divided into two classes—those in Figure 9, which respond only to heat stress from the environment, and those in Figure 10, which respond to both the heat stress from the environment and the resultant heat strain (Stolwijk *et al.* 1968).

For warm environments, any index with isotherms parallel to skin temperature is a reliable index of thermal sensation alone, and not of discomfort caused by increased humidity. Indices with isotherms parallel to ET* are reliable indicators of discomfort or dissatisfaction with thermal environments. For a fixed exposure time to cold, lines of constant t_{sk}, ET*, and t_o are essentially identical, and cold sensation is no different from cold discomfort. For a state of comfort with sedentary or light activity, lines of constant t_{sk} and ET* coincide. Thus comfort and thermal sensations coincide in this region as well. The upper and lower temperature limits for comfort at these levels can be specified either by thermal sensation (Fanger 1982) or by ET*, as is done in ASHRAE *Standard* 55-92, since lines of constant comfort and lines of constant thermal sensation should be identical. Figure 5 shows comfort zones for summer and winter; they are intended to provide acceptable conditions for occupants wearing typical indoor clothing and at or near sedentary activity.

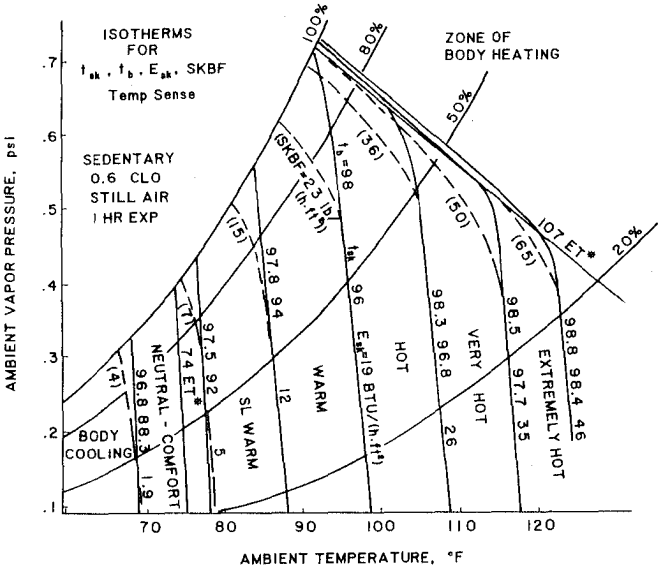

Fig. 9 Effect of Environmental Conditions on Physiological Variables

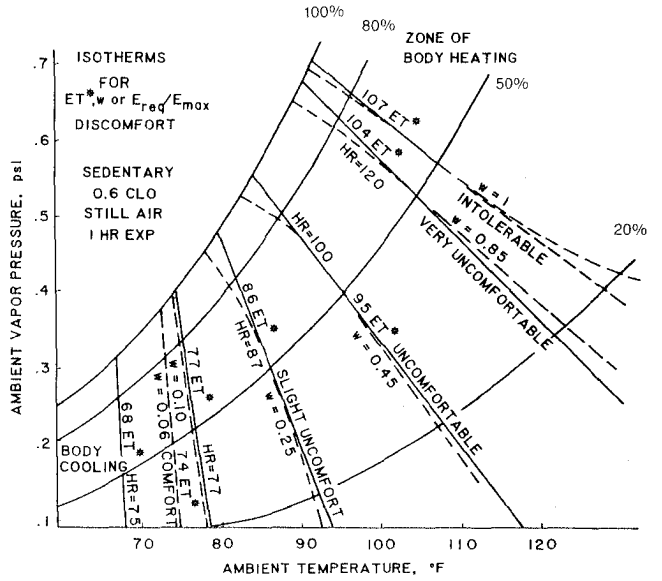

Fig. 10 Effect of Thermal Environment on Discomfort

Individual Variations

No single environment is judged satisfactory by everybody, even if they are wearing identical clothing and performing the same activity. The comfort zone specified in ASHRAE *Standard* 55-92 is based on 90% acceptance, or 10% dissatisfied. Fanger (1982) related the predicted percent dissatisfied (PPD) to the PMV as follows:

$$PPD = 100 - 95\exp[-(0.03353\,PMV^4 + 0.2179\,PMV^2)] \quad (82)$$

where dissatisfied is defined as anybody not voting either −1, +1, or 0. This relationship is shown in Figure 11. A PPD of 10% corresponds to the PMV range of ±0.5, and even with PMV = 0, about 5% of the people are dissatisfied.

Day-to-Day Variations

Fanger (1973) conducted an experiment with a group of subjects, where the preferred ambient temperature for each subject under identical conditions was determined on four different days. Since the standard deviation was only 1.0 °F, Fanger concluded that the comfort conditions for the individual can be reproduced and will vary only slightly from day to day.

Age

Because metabolism decreases slightly with age, many have stated comfort conditions based on experiments with young and healthy subjects cannot be used for other age groups. Fanger (1982), Fanger and Langkilde (1975), Langkilde (1979), Nevins *et al.* (1966), and Rohles and Johnson (1972) conducted comfort studies in Denmark and the United States on different age groups (mean age 21 to 84). The studies revealed that the thermal environments preferred by older people do not differ from those preferred by younger people. The lower metabolism in older people is compensated for by a lower evaporative loss. Collins and Hoinville (1980) confirmed these results.

The fact that young and old people prefer the same thermal environment does not necessarily mean they are equally sensitive when exposed to cold or heat. In practice, the ambient temperature level in the homes of older people is often higher than that for younger people. This may be explained by the lower activity of elderly people, who are normally sedentary for a greater part of the day.

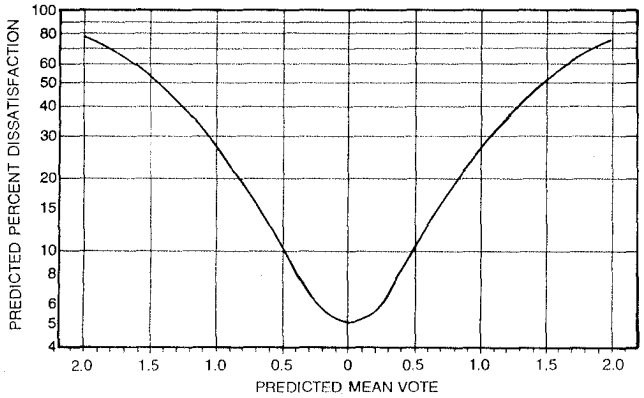

Fig. 11 Predicted Percentage of Dissatisfied (PPD) as Function of Predicted Mean Vote (PMV)

Adaptation

Many believe that people can acclimatize themselves by exposure to hot or cold surroundings, so that they prefer other thermal environments. Fanger (1982) conducted experiments involving subjects from the United States, Denmark, and tropical countries. The latter group was tested in Copenhagen immediately after their arrival by plane from the tropics where they had lived all their lives. Other experiments were conducted for two groups exposed to cold daily. One group comprised subjects who for 8 h daily for at least one year were doing sedentary work in cold surroundings (in the meat-packing industry). The other group consisted of winter swimmers who bathed in the sea daily.

Only slight differences regarding both the preferred ambient temperature and the physiological parameters in the comfort conditions were reported for the various groups. These results indicate that people cannot adapt to preferring warmer or colder environments. It is therefore likely that the same comfort conditions can be applied throughout the world. However, in determining the preferred ambient temperature from the comfort equations, a clo-value that corresponds to the local clothing habits should be used. A comparison of field comfort studies from different parts of the world shows significant differences in clothing habits depending on, among other things, the outdoor climate (Nichol and Humphreys 1972). According to these results, adaptation has little influence on the preferred ambient temperatures. In uncomfortable warm or cold environments, there will, however, often be an influence of adaptation. People used to working and living in warm climates can more easily accept and maintain a higher work performance in hot environments than people from colder climates.

Sex

Previously cited experiments by Fanger (1982), Fanger and Langkilde (1975), and Nevins *et al.* (1966) use equal numbers of male and female subjects, so comfort conditions for the two sexes can be compared. The experiments show that men and women prefer almost the same thermal environments. Women's skin temperature and evaporative loss are slightly lower than those for men, and this balances the somewhat lower metabolism of women. The reason that women often prefer higher ambient temperatures than men may be explained by the lighter clothing normally worn by women.

Seasonal and Circadian Rhythms

Since people cannot adapt to prefer warmer or colder environments, it follows that there is no difference between comfort conditions in winter and in summer. McNall *et al.* (1968) confirmed this in an investigation where results of winter and summer experiments showed no difference. On the other hand, it is reasonable to expect the comfort conditions to alter during the day as the internal body temperature has a daily rhythm—a maximum occuring late in the afternoon, and a minimum early in the morning.

In determining the preferred ambient temperature for each of 16 subjects both in the morning and in the evening, Fanger *et al.* (1974) and Ostberg and McNicholl (1973) observed no difference. Furthermore, Fanger *et al.* (1973) found only small fluctuations in the preferred ambient temperature during a simulated 8-h workday (sedentary work). There is a slight tendency to prefer somewhat warmer surroundings before lunch, but none of the fluctuations is significant.

Local Thermal Discomfort

As predicted by the comfort equation (PMV = 0), thermal neutrality is not the only condition for thermal comfort. A person may feel thermally neutral for the body as a whole, but might not be comfortable if one part of the body is warm and another cold. Therefore, thermal comfort also requires that no local warm or cold discomfort exists at any part of the human body. Such local discomfort may be caused by an asymmetric radiant field (cold windows, warm heaters); by local convective cooling (draft); by contact with a hot or cold floor; or by a vertical air temperature difference between the feet and the head.

Asymmetric Thermal Radiation

Asymmetric or nonuniform thermal radiation in a space may be caused by cold windows, uninsulated walls, cold products, cold or warm machinery, or by improperly sized panels on the wall or ceiling. In residential buildings, offices, restaurants, etc., the most common reasons for discomfort due to asymmetric thermal radiation are large windows in the winter or improperly sized or installed ceiling heating panels. At industrial workplaces, the reasons include cold or warm products, cold or warm equipment, etc.

Among the studies conducted on the influence of asymmetric thermal radiation are those by McIntyre (1974, 1976), McIntyre and Griffiths (1975), Fanger and Langkilde (1975), McNall and Biddison (1970), and Olesen *et al.* (1972). These studies all used seated subjects. The recommendations in the existing comfort standards (ISO 7730, ASHRAE 55-92) are based on studies reported by Fanger *et al.* (1980) and Fanger and Christensen (1985), and include guidelines regarding the radiant temperature asymmetry from an overhead warm surface (heated ceiling) and a vertical cold surface (cold window).

To establish a relationship between the radiant temperature asymmetry and the sensation of comfort or discomfort, human subjects were seated, dressed in standard clothing (approximately 0.6 clo), and exposed to either an overhead warm surface or a vertical cold surface from one side. During the experiments, the radiant temperature asymmetry was increased by increasing the temperature of the overhead warm surface or decreasing the temperature of the vertical cold surface. The temperature of all other surfaces in the climatic chamber was kept equal to the air temperature. Changing the temperature on the warm/cold surface also influenced the mean radiant temperature and then the general thermal sensation of the subjects. This was, however, compensated for by changing the air temperature according to the subjects' wishes. In this way, they were always in thermal neutrality and exposed only to the discomfort resulting from excessive asymmetry.

The subjects gave their reactions on their comfort sensation, and a relationship between the radiant temperature asymmetry and the number of subjects feeling dissatisfied was established. Note that the percentages of dissatisfied have nothing to do with the PPD-index, which predicts the percentage of dissatisfied due to a general warm or cold sensation. In all the experiments, the subjects were in thermal neutrality so the percentage of people feeling generally uncomfortably warm or cold (PPD-value) cannot be added and assumed to be equal to the total number of people feeling dissatisfied. Figure 12 shows that people are more sensitive to the asymmetry caused by an overhead warm surface than by a vertical cold surface. The influence of an overhead cold surface and a vertical warm surface is much less. These data are particularly important when applying radiant panels to provide comfort in spaces with large cold surfaces or cold windows.

Draft

Draft is an undesired local cooling of the human body caused by air movement. This is a serious problem, not only in many ventilated buildings but also in automobiles, trains, and aircraft. Draft has been identified as one of the most annoying factors in offices. When people sense draft, it often results in a demand for higher air temperatures in the room or for stopping ventilation systems.

Rohles *et al.* (1974), Ostergaard *et al.* (1974), and Burton *et al.* (1975) investigated the convective heat loss for the entire body as

a function of air velocity. However, this information is of limited value for predicting a local cooling felt as a draft. A person may feel thermally neutral for the body as a whole, yet may not be comfortable if air movements cause an unwanted cooling of a particular part of the body.

Houghton (1938) studied ten male subjects exposed to constant local velocities at the back of the neck and at the ankles; McIntyre (1979) exposed the head to constant local velocities; and Fanger and Pedersen (1977) exposed subjects to a periodically fluctuating airflow directed towards the back of the neck or the ankles. The latter showed that fluctuating airflow is more uncomforable than a constant flow. In real spaces, occupants are not exposed to a well-defined, periodically fluctuating airflow. Rather, in practice, fluctuations are stochastical. In field studies by Thorshauge (1982), Hanzawa *et al.* (1987), and Melikow *et al.* (1988), fluctuations were determined in ventilated spaces.

To establish the scientific basis required to predict human response to fluctuating air velocities as they occur in practice, Fanger and Christensen (1985) aimed to establish the percentage of the population feeling draft when exposed to a given mean velocity. Figure 13 shows the percentage of subjects who felt draft on the head region (the dissatisfied) as a function of the mean velocity at the neck. The head region comprises head, neck, shoulders, and back. The air temperature had a significant influence on the percentage of dissatisfied. There was no significant difference between responses of men and women to draft. The data in Figure 13 applies, therefore, only to persons wearing normal indoor clothing and performing light, mainly sedentary work. Persons with higher activity levels are not so sensitive to draft (Jones *et al.* 1986).

In another study, Fanger *et al.* (1987) investigated the effect of turbulence intensity on sensation of draft. The turbulence intensity had a significant effect on the occurrence of draft sensation. The following model predicts the percentage of people dissatisfied because of draft intensity. The model can be used for quantifying draft risk in spaces and for developing air distribution systems with a low draft risk.

$$PD = 0.06533\,(93.2 - t_a)\,(V - 9.8)^{0.622} + 3.90 \times 10^{-5}\,(93.2 - t_a)\,(V - 9.8)^{0.622}\,V\,Tu \qquad (83)$$

For $V < 9.8$ fpm, insert $V = 9.8$ and for PD > 100%, insert PD = 100% where Tu is the turbulence intensity defined by:

$$Tu = 100\,\frac{V_{sd}}{V} \qquad (84)$$

and V_{sd} is the standard deviation of the velocity measured with an omnidirectional anemometer having a 0.2-s time constant.

The model extends the Fanger and Christensen draft chart model to include turbulence intensity. In this study, Tu decreases when V increases. This means that the effect of V for the experimental data to which the model is fitted are: $68 < t_a < 79$°F, $10 < V < 100$ fpm, and $0 < Tu < 70$%. Figure 14 gives more precisely the curves that result from intersections between planes of constant Tu and the surfaces of PD = 15%.

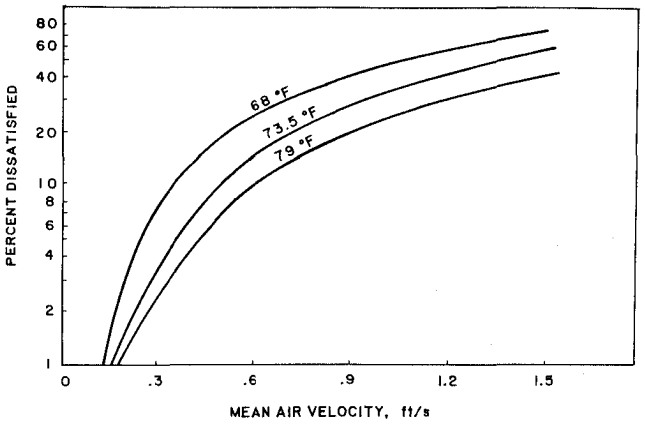

Fig. 13 Percentage of People Dissatisfied as Function of Mean Air Velocity

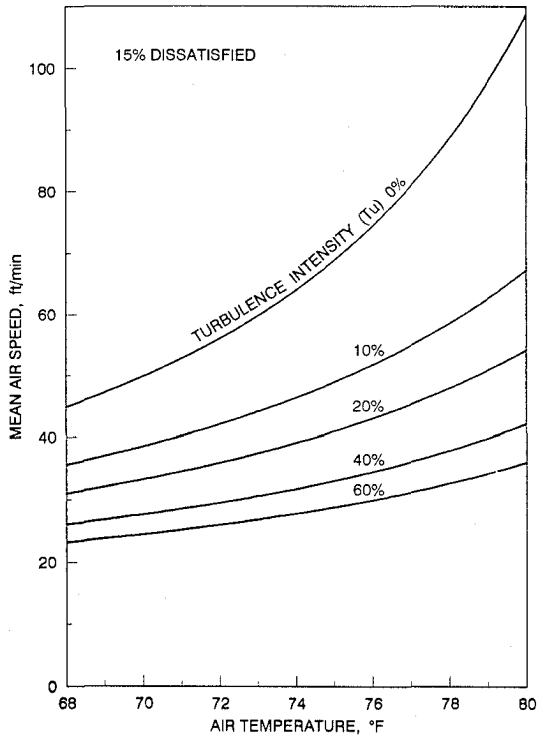

Fig. 14 Draft Conditions Dissatisfying 15% of Population

Vertical Air Temperature Difference

In most spaces in buildings, the air temperature normally increases with height above the floor. If the gradient is sufficiently large, local warm discomfort can occur at the head, and/or cold discomfort can occur at the feet, although the body as a whole is thermally neutral. Among the few studies of vertical air temperature differences and the influence of thermal comfort reported are Olesen *et al.* (1979), McNair (1973), McNair and Fishman (1974), and Eriksson *et al.* (1975). Subjects were seated in a climatic chamber so they were individually exposed to different air temperature differences between head and ankles (Olesen *et al.* 1979). During the tests, the subjects were in thermal neutrality because they were allowed to change the temperature level in the test room whenever they desired; the vertical temperature difference, however, was kept unchanged. The subjects gave subjective reactions to their thermal sensation, and Figure 15 shows the percentage of dissatisfied as a function of the vertical air temperature difference between head (43 in. above the floor) and ankles (4 in. above the floor).

The case where the air temperature at head level is lower than that at ankle level will not be as critical for the occupants. Eriksson (1975) indicated that his subjects could tolerate much greater differences if the head were cooler. This observation is verified in the experiments with asymmetric thermal radiation from a cooled ceiling (Fanger *et al.* 1985).

Warm or Cold Floors

Due to the direct contact between the feet and the floor, local discomfort of the feet can often be caused by a too-high or too-low floor temperature. Also, the floor temperature has a significant influence on the mean radiant temperature in a room. The floor temperature is greatly influenced by the way a building is constructed (*e.g.*, insulation of the floor, above a cellar, directly on the ground, above another room, use of floor heating, floors in radiant heated areas). If a floor is too cold and the occupants feel cold discomfort in their feet, a common reaction is to increase the temperature level in the room; in the heating season, this also increases energy consumption. A radiant system, which will radiantly heat the floor, is another method used to avoid discomfort from cold floors.

The influence of floor temperature on feet comfort has been reported by Nevins *et al.* (1958, 1964, 1967), Olesen (1977a, 1977b), Frank (1959), Cammerer and Schule (1960), Schule and Monroe (1971), Schule (1954), and Missenard (1955). The most extensive studies were performed by Olesen (1977a, 1977b), who, based on his own experiments and reanalysis of the data from Nevins *et al.*, recorded the following results. For floors occupied by people with bare feet (in swimming halls, gymnasiums, dressing rooms, bathrooms, and bedrooms), flooring material is important. Ranges for some typical floor materials are as follows:

Textiles (rugs)	70 to 82 °F
Pinewood floor	72.5 to 82 °F
Oakwood floor	76 to 82 °F
Hard linoleum wood	75 to 82 °F
Concrete	79 to 83 °F

To save energy, flooring materials with a low contact coefficient (cork, wood, carpets), radiant heated floors, or floor heating systems can be used to eliminate a desire for higher ambient temperatures caused by cold feet. These recommendations should also be followed in schools, where the children often play directly on the floor.

For floors occupied by people with normal indoor footwear, flooring material is insignificant. Olesen (1977b) found an optimal temperature of 77 °F for sedentary and 73.5 °F for standing or walking persons. At the optimal temperature, 6% of the occupants felt warm or cold discomfort in the feet. Figure 16 shows the relationship between floor temperature and percentage of dissatisfied, combining data from experiments with seated and standing subjects. In all experiments, the subjects were in thermal neutrality; thus, the percentage of dissatisfied is only related to the discomfort due to cold or warm feet. Again, no significant difference in floor temperature was preferred by females and males.

SPECIAL ENVIRONMENTS

Infrared Heating

Optical and thermal properties of skin must be considered in studies concerning the effects of infrared radiation in (1) producing changes in skin temperature and skin blood flow, and (2) evoking sensations of temperature and comfort (Hardy 1961). Although the body can be considered to have the properties of water, thermal sensation and heat transfer with the environment require a study of the skin and its interaction with visible and infrared radiation.

Figure 17 shows how skin reflectance and absorptance vary for a blackbody heat source at the temperature (in °R) indicated. These curves show that darkly pigmented skin is heated more by direct radiation from a high-intensity heater at 4500 °R than is lightly pigmented skin. With low-temperature and low-intensity heating equipment used for total area heating, there is minimal, if any, difference. Also, in practice, clothing minimizes differences.

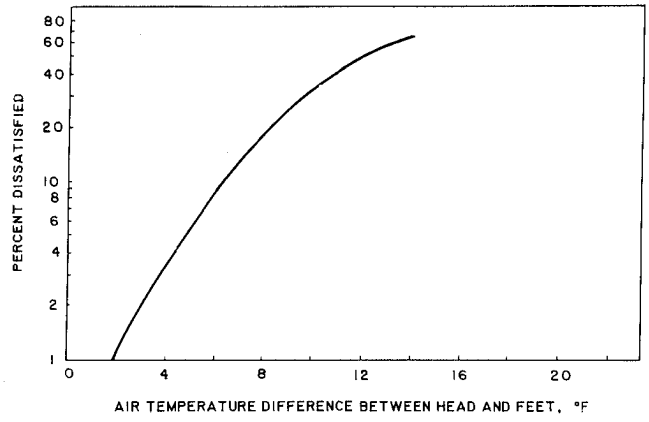

Fig. 15 Percentage of People Dissatisfied as Function of Vertical Air Temperature Difference between Head and Ankles

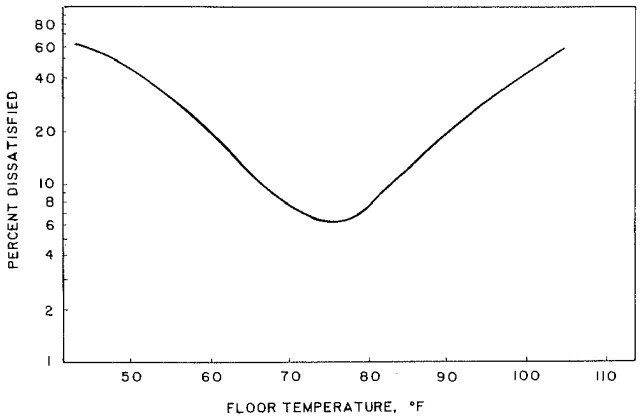

Fig. 16 Percentage of People Dissatisfied as Function of Floor Temperature

Changes in skin temperature caused by high-intensity infrared radiation depend on the thermal conductivity, density, and specific heat of the living skin (Lipkin and Hardy 1954). Modeling of skin heating with the heat transfer theory yields a parabolic relation between exposure time and skin temperature rise for nonpenetrating radiation:

$$t_{sf} - t_{si} = \Delta t = 2J\epsilon\sqrt{\theta/(\pi k\rho c_p)} \quad (85)$$

where

t_{sf} = final skin temperature, °F
t_{si} = initial skin temperature, °F
J = irradiation intensity from source at °R, Btu/(h·ft²)
θ = time, h
k = specific thermal conductivity of tissue, Btu/(h·ft·°R)
ρ = density, lb/ft³
c_p = specific heat, Btu/(lb·°R)
ϵ = skin absorptance for radiation at °R, dimensionless

Product $k\rho c_p$ is the physiologically important quantity that determines temperature elevation of skin or other tissue on exposure to nonpenetrating radiation. Fatty tissue, because of its relatively low specific heat, is heated more rapidly than moist skin or bone. Experimentally, $k\rho c_p$ values can be determined by plotting Δt^2 against 1.13 $J^2\theta$ (Figure 18). Lines are linear and their slopes are inversely proportional to the $k\rho c_p$ of the specimen. Comparing leather and water with body tissues suggests that thermal inertia values depend largely on tissue water content.

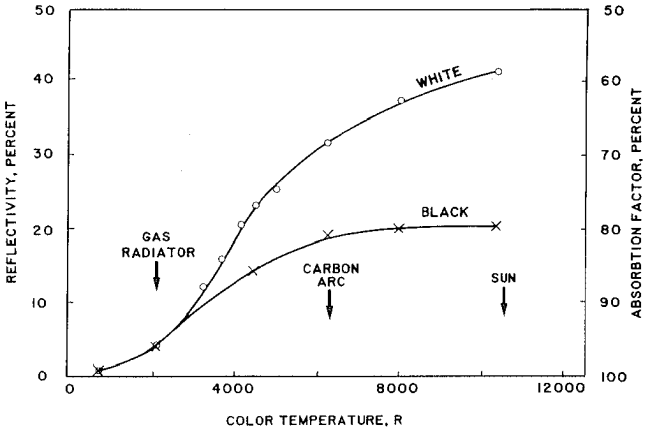

Fig. 17 Variation in Skin Reflection and Absorptivity for Blackbody Heat Sources

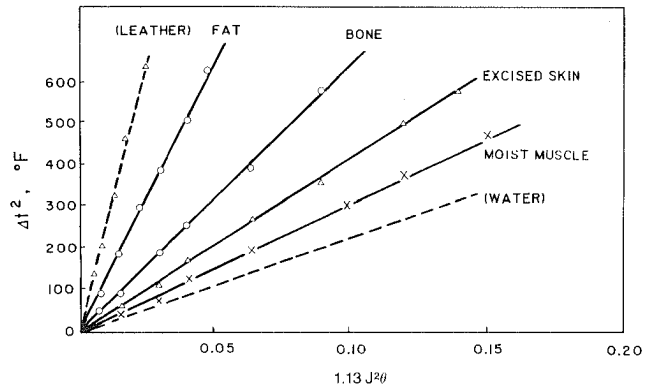

Fig. 18 Comparing Thermal Inertia of Fat, Bone, Moist Muscle, and Excised Skin to that of Leather and Water

Living tissues do not conform strictly to this simple mathematical formula. Figure 19 compares excised skin with living skin with normal blood flow, and skin with blood flow occluded. For short exposure times, the $k\rho c_p$ of normal skin is the same as that in which blood flow has been stopped; excised skin heats more rapidly due to unavoidable dehydration that occurs postmortem. However, with longer exposure to thermal radiation, vasodilatation increases blood flow, cooling the skin. For the first 20 s of irradiation, skin with normally constricted blood vessels has a $k\rho c_p$ value of one-fourth that for skin with fully dilated vessels.

Skin temperature is the best single index of thermal comfort. The most rapid changes in skin temperature occur during the first 60 s of exposure to infrared radiation. During this initial period, thermal sensation and the heating rate of the skin vary with the quality of infrared radiation (color temperature in degrees Rankine). Since radiant heat from a gas-fired heater is absorbed at the skin surface, the same unit level of absorbed radiation during the first 60 s of exposure can cause an even warmer initial sensation than penetrating solar radiation. Because skin heating curves tend to level off after a 60 s exposure (Figure 19), a relative balance is quickly created between heat absorbed, heat flow to the skin surface, and heat loss to the ambient environment. Therefore, the effects of radiant heating on thermal comfort should be examined for conditions approaching thermal equilibrium.

Stolwijk and Hardy (1966) described an unclothed subject's response for a 2-h exposure to temperatures of 41 to 95 °F. Nevins *et al.* (1966) showed a relation between ambient temperatures and thermal comfort of clothed, resting subjects. For any given uniform environmental temperature, both initial physiological response and degree of comfort can be determined for a subject at rest.

Physiological implications for radiant heating can be defined by two environmental temperatures: (1) mean radiant temperature or $\bar{t}_r$, and (2) ambient air temperature t_a. For this discussion on radiant heat, assume that (1) relative humidity is less than 50%, and (2) air movement is low and constant, with an equivalent convection coefficient of 0.51 Btu/(h·ft²·°F).

The equilibrium equation, describing heat exchange between skin surface at mean temperature t_{sk} and the radiant environment, is given in Equation (28), and can be transformed to give (see Table 2):

$$M' - E_{sk} - F_{cle}[h_r(t_{sk} - \bar{t}_r) + h_c(t_{sk} - t_a)] = 0 \quad (86)$$

where M' is the net heat production ($M - W$) less respiratory losses.

By algebraic transformation, Equation (86) can be rewritten:

$$M' + h_r(\bar{t}_r - t_a)F_{cle} = E_{sk} + (h_r + h_c)(t_{sk} - t_a)F_{cle} \quad (87)$$

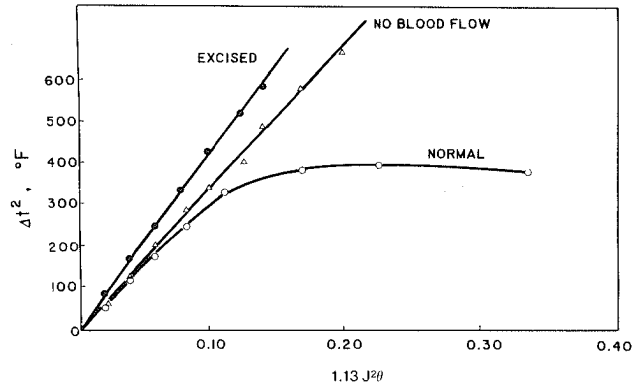

Fig. 19 Thermal Inertias of Excised, Bloodless, and Normal Living Skin

In Equation (87), the factor common to both terms describing dry heat exchange is the ambient temperature t_a. In the left-hand term, $\bar{t}_r$ is related to t_a independent of t_{sk}; in the right, t_{sk} is related to t_a independent of $\bar{t}_r$.

The last term in Equation (87) describes heat exchange with an environment uniformly heated to temperature t_a. The term h_r, evaluated in Equation (50), is also a function of posture, for which factor A_r/A_D can vary from 0.67 for crouching to 0.73 for standing. For preliminary analysis, a useful value for h_r is 0.83 Btu/(h·ft²·°F), which corresponds to a normally clothed (at 75 °F) sedentary subject. Ambient air movement affects h_c, which appears only in the right-hand term of Equation (87).

The radiation term on the left in Equation (87) describes the net radiation exchange caused by the presence of a warm panel; an infrared electric or gas heater; a cold wall, floor, or window; or any surface with a temperature different from the air temperature. When $\bar{t}_r$ equals t_a, the result is the same as inside an enclosure at uniform temperature t_a. The radiation term on the left in Equation (87) is the basis for defining *effective radiant field* (ERF), which is the net radiant energy absorbed on the exposed body surface of a human-shaped object, with a surface temperature of uniform value t_a. This field energy term (1) is a function of body position, (2) is independent of air movement, (3) as an energy, adds to metabolism M, and (4) is modified by factor F_{cl} with clothing, and by absorptivity of the clothing surface.

Although linear radiation coefficient h_r is used in Equations (86) and (87), the same definition of ERF follows if the fourth power radiation law is used. By this law, assuming emissivity of the body surface is unity, the ERF term in Equation (87) is now:

$$\text{ERF} = \sigma(A_r/A_D)[(\bar{t}_r + 460)^4 - (t_a + 460)^4]F_{cle} \qquad (88)$$

Since $\bar{t}_r$ equals the radiation of several surfaces at different temperatures (T_1, T_2, ···, T_j); then:

$$\begin{aligned}\text{ERF} = \sigma(A_r/A_D)[&\epsilon_1 F_{m-1}(T_1^4 - T_a^4) \\ &+ \epsilon_2 F_{m-2}(T_2^4 - T_a^4) \\ &+ \cdots + \epsilon_j F_{m-j}(T_j^4 - T_a^4)]F_{cle}\end{aligned} \qquad (89)$$

where

σ = Stefan-Boltzmann constant, 0.1714×10^{-8} Btu/(h·ft²·°R⁴)
ϵ_j = emissivity of skin or clothing surface for source radiating at temperature T_j
F_{m-j} = angle factor to subject m from source j
T_a = ambient air temperature, °R

$$\text{ERF} = (\text{ERF})_1 + (\text{ERF})_2 + \cdots + (\text{ERF})_j \qquad (90)$$

where any $(\text{ERF})_j$ is given by:

$$(\text{ERF})_j = \sigma(A_r/A_D)\epsilon_j F_{m-j}(T_j^4 - T_a^4)F_{cle}$$

ERF is the sum of the fields caused by each surface T_j [*e.g.*, T_1 may be an infrared beam heater; T_2, a heated floor; T_3, a warm ceiling; T_4, a cold plate glass window ($T_4 < T_a$); etc.]. Only surfaces with temperature T_j differing from T_a contribute to the ERF.

Comfort Equations for Radiant Heating

The *comfort equation for radiant heat* (Gagge *et al.* 1967a, 1967b) follows from Equation (87):

$$t_o\,(\text{for comfort}) = t_a + \text{ERF}\,(\text{for comfort})/h \qquad (91)$$

Thus, operative temperature for comfort is the temperature of the ambient air plus a temperature increment ERF/h, a ratio that measures the effectiveness of the incident radiant heating on occupants. Higher air movement (greater values of h or h_c) reduces the effectiveness of radiant heating systems. Clothing lowers t_o for comfort and for thermal neutrality.

Values for ERF and h must be determined to apply the comfort equation for radiant heating. Table 3 may be used to estimate h. One method of determining ERF is to calculate it directly from radiometric data that give, (1) radiation emission spectrum of the source, (2) concentration of the beam, (3) radiation from the floor, ceiling, and windows, and (4) corresponding angle factors involved. This analytical approach is described in Chapter 48 of the 1991 ASHRAE *Handbook—Applications*.

For direct measurement, a skin-colored or black globe, 6 in. in diameter, can measure the radiant field ERF for comfort, in terms of the uncorrected globe temperature t_g in °F and air movement in fpm, by the following relation:

$$\text{ERF} = (A_r/A_D)[1.07 + 0.169\sqrt{V}](t_g - t_a)\ \text{in Btu/(h·ft}^2\text{)} \qquad (92)$$

The average value of A_r/A_D is 0.7. For a skin-colored globe, no correction is needed for the quality of radiation. For a black globe, ERF must be multiplied by ϵ for the exposed clothing/skin surface. For a subject with 0.6 to 1.0 clo, t_o for comfort should agree numerically with t_a for comfort in Figure 5. When t_o replaces t_a in Figure 5, humidity is measured in psi vapor pressure rather than relative humidity, which refers only to air temperature.

Other methods may be used to measure ERF. The most accurate is by physiological means. In Equation (87), when M, $t_{sk} - t_a$, and the associated transfer coefficients are experimentally held constant:

$$\Delta E = \Delta\text{ERF} \qquad (93)$$

The variation in evaporative heat loss (rate of weight loss) caused by changing the wattage of two T-3 infrared lamps is a measure in absolute terms of the radiant heat received by the body.

A third method uses a directional radiometer to measure ERF directly. For example, radiation absorbed at the body surface [in Btu/(h·ft²·°F)] is:

$$\text{ERF} = \epsilon(A_i/A_D)J \qquad (94)$$

where irradiance J can be measured by a directional (Hardy-type) radiometer; ϵ is the surface absorptance effective for the source used; and A_i is the projection area of the body normal to the directional irradiance. Equation (94) can be used to calculate ERF only for the simplest geometrical arrangements. For a human subject lying supine and irradiated uniformly from above, A_i/A_D is 0.3. Figure 17 shows variance of ϵ for human skin with blackbody temperature (in °R) of the radiating source. When irradiance J is uneven and coming from many directions, as is usually the case, the previous physiological method can be used to obtain an effective A_i/A_D from the observed ΔE and $\Delta(\epsilon J)$.

Hot and Humid Environments

Tolerance limits to high temperature vary with the ability to (1) sense temperature, (2) lose heat by regulatory sweating, and (3) move heat from the body core by blood flow to the skin surface, where cooling is the most effective. Many interrelating processes are involved in heat stress (Figure 20).

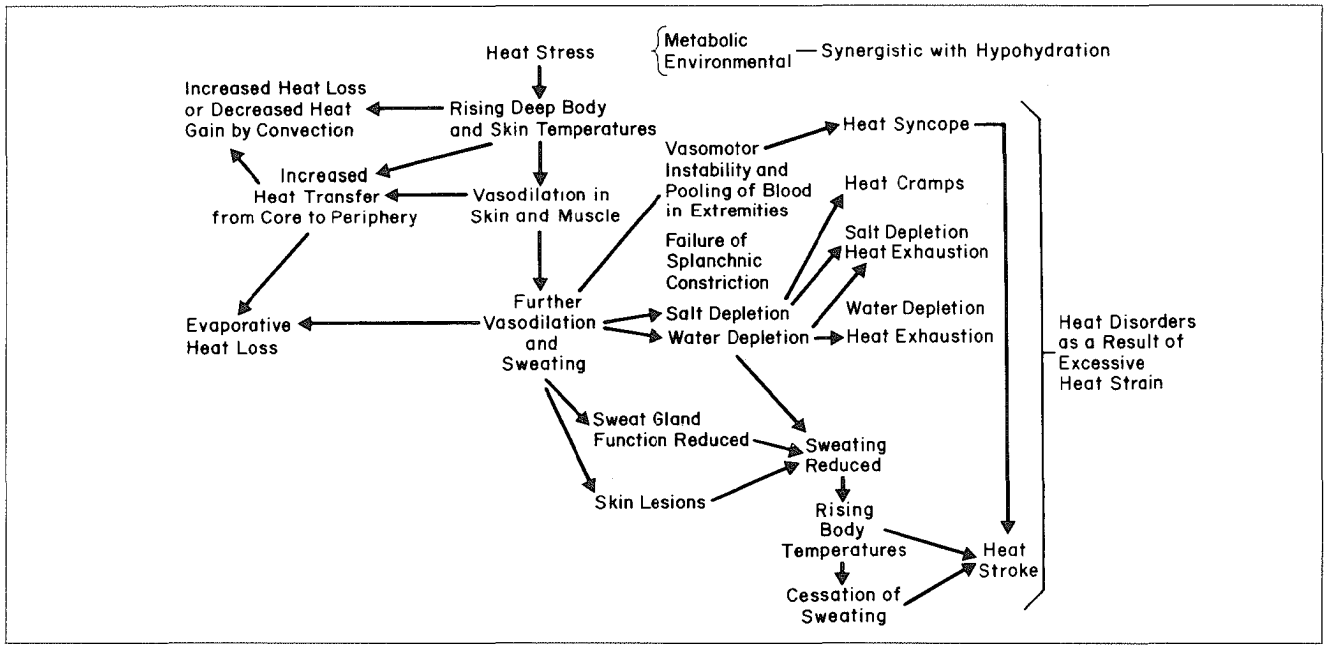

Fig. 20 Schematic Design of Heat Stress and Heat Disorders
[Modified by Buskirk from scale diagram by Belding (1967) and Leithead and Lind (1964)]

Skin surface temperatures of 115 °F trigger pain receptors in the skin; direct contact with metal at this temperature is painful. However, since thermal insulation of the air layer around the skin is high, much higher dry air temperatures can be tolerated. For lightly clothed subjects at rest, tolerance times of nearly 50 min have been reported at 180 °F dry-bulb temperature; 33 min at 200 °F; 26 min at 220 °F; and 24 min at 240 °F. In each case, dew points were lower than 86 °F. Many individuals are stimulated by brief periods of exposure to 185 °F dry air in a sauna. Short exposures to these extremely hot environments are tolerable because of cooling by sweat evaporation. However, when ambient vapor pressure approaches 0.87 psi (97 °F dew point, typically found on sweating skin), tolerance is drastically reduced. Temperatures of 122 °F can be intolerable if the dew-point temperature is greater than 77 °F and both deep body temperature and heart rate rise rapidly within minutes (Gonzalez *et al.* 1978).

The rate and length of time a body can sweat are limited. The maximum rate of sweating for an average man is about 4 lb/h. If all this sweat evaporates from the skin surface under conditions of low humidity and air movement, maximum cooling is about 214 Btu/(h · ft^2 · °F). However, this value does not normally occur because sweat rolls off the skin surface without evaporative cooling or is absorbed by or evaporated within clothing. A more typical cooling limit is 6 mets, 110 Btu/(h · ft^2 · °F), representing approximately 2.4 lb/h of sweating for the average man.

Thermal equilibrium is maintained by dissipation of resting heat production (1 met) plus any radiant and convective load. If the environment does not limit heat loss from the body during heavy activity, decreasing skin temperature compensates for the core temperature rise. Therefore, mean body temperature is maintained, although the gradient from core to skin is increased. Blood flow through the skin is reduced, but muscle blood flow necessary for exercise is preserved. The upper limit of skin blood flow ($\dot{m}_{bl}$) is about 200 lb/h (Burton and Bazett 1936).

Body heat storage of 318 Btu (or a rise in t_b of 2.5 °F) for an average-sized man represents an average voluntary tolerance limit. Continuing work beyond this limit increases the risk of heat exhaustion. Collapse can occur at about 635 Btu of storage (5 °F); few individuals can tolerate heat storage of 872 Btu (6.8 °F above normal).

The cardiovascular system affects tolerance limits. In normal, healthy subjects exposed to extreme heat, heart rate and cardiac output increase in an attempt to maintain blood pressure and supply of blood to the brain. At a heart rate of about 180 bpm, the short time between contractions prevents adequate blood supply to the heart chambers. As heart rate continues to increase, cardiac output drops, causing inadequate convective blood exchange with the skin and, perhaps more important, inadequate blood supply to the brain. Victims of this heat exhaustion faint or black out. Accelerated heart rate can also result from inadequate venous return to the heart caused by pooling of blood in the skin and lower extremities. In this case, cardiac output is limited because not enough blood is available to refill the heart between beats. This occurs most frequently when an overheated individual, having worked hard in the heat, suddenly stops working. The muscles no longer massage the blood back past the valves in the veins toward the heart. Dehydration compounds the problem, since fluid volume in the vascular system is reduced.

If core temperature increases above 106 °F, critical hypothalamic proteins can be damaged, resulting in inappropriate vasoconstriction, cessation of sweating, increased heat production by shivering, or some combination of these. Heat stroke damage is frequently irreversible and carries a high risk of fatality.

A final problem, hyperventilation, occurs predominantly in hot-wet conditions, when too much CO_2 is washed from the blood. This can lead to tingling sensations, skin numbness, and vasoconstriction in the brain with occasional loss of consciousness.

Since a rise in heart rate or rectal temperature is essentially linear with ambient vapor pressure above a dew-point temperature of 77 °F, these two changes can measure severe heat stress. Although individual heart rate and rectal temperature responses to mild heat stress vary, severe heat stress saturates physiological regulating systems, producing uniform increases in heart rate and rectal temperature. In contrast, sweat production measures stress under milder conditions but becomes less useful under more severe stress. The maximal sweat rate compatible with body cooling varies with (1) degree of heat acclimatization, (2) duration of sweating, and (3) whether the sweat evaporates or merely saturates the skin and drips off. Total sweat rates in excess of 4.4 lb/h can occur in short

exposures, but about 2.2 lb/h is an average maximum level sustainable for an acclimatized man.

Figure 21 illustrates the decline in heart rate, rectal temperature, and skin temperature when exercising subjects are exposed to 104 °F over a period of days. Acclimatization can be achieved by working in the heat for 100 min each day—30% improvement occurs after the first day, 50% after 3 days, and 95% after 6 or 7 days. Increased sweat secretion while working in the heat can be induced by rest. Although reducing salt intake during the first few days in the heat can conserve sodium, heat cramps may result. Working regularly in the heat improves cardiovascular efficiency, sweat secretion, and sodium conservation. Once induced, heat acclimatization can be maintained by as few as once-a-week workouts in the heat; otherwise, it diminishes slowly over a 2- to 3-week period and disappears.

Extreme Cold Environments

Human performance in extreme cold ultimately depends on maintaining thermal balance. Whether at work or at rest, a body exposed to cold can lose heat faster than it produces heat for only a limited time. Subjective discomfort is reported by an average 154-lb man with 2800 in^2 of body surface area, when a heat debt of about 100 Btu is incurred. A heat debt of about 600 Btu is acutely uncomfortable; this represents a drop of approximately 4.7 °F (or about 7% of total heat content) in mean body temperature.

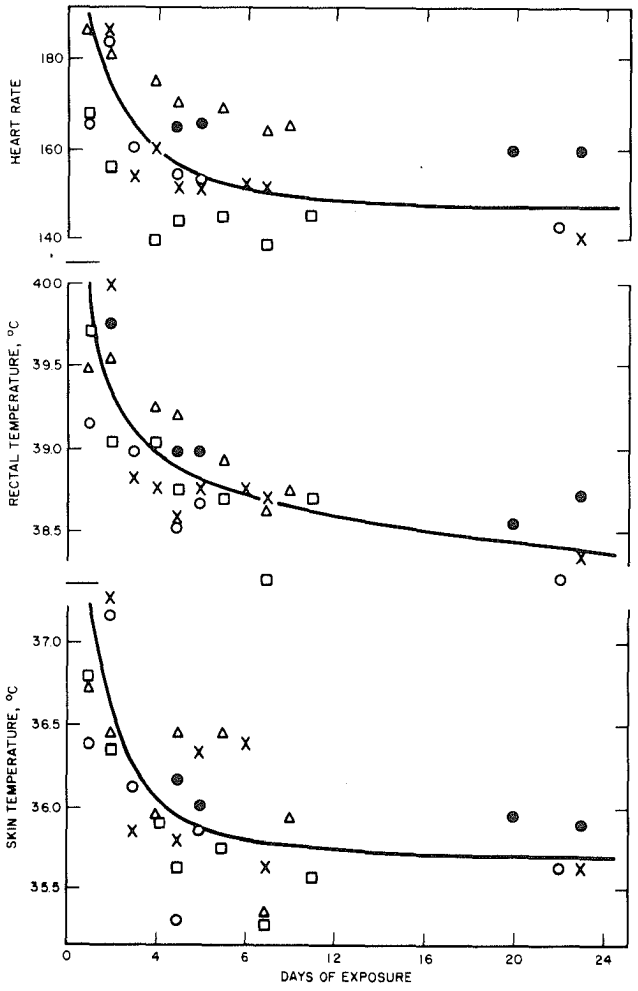

Fig. 21 Acclimatization to Heat Resulting from Daily Exposure of Five Subjects to Room Maintained at 40 °C with 23% rh
(Robinson *et al.* 1943)

This loss can occur during 1 to 2 h of sedentary activity outdoors. A sleeping individual will awake after losing about 300 Btu, decreasing mean skin temperature by about 5.5 °F and deep body temperature by about 1 °F, using the Burton relationship [$\alpha = 0.67$, in Equation (41)]. A drop in deep body temperature (*e.g.*, rectal temperature) below 95 °F threatens a loss of body temperature regulation, while 82.4 °F is considered critical for survival, despite recorded survival from a deep body temperature of 64.4 °F. Temperature is more crucial than rate of temperature change; Witherspoon *et al.* (1971) observed a rate of fall in the core temperature of 5.4 °F per hour in subjects immersed in 50 °F water, without residual effect.

Activity level also affects human performance. Subjective sensations, reported by sendentary subjects at a mean skin temperature of 92 °F, are *comfortable*; at 88 °F, *uncomfortably cold*; at 86 °F, *shivering cold*; and at 84 °F, *extremely cold*. The critical subjective tolerance limit (without numbing) for mean skin temperature appears to be about 77 °F. However, during moderate to heavy activity, subjects reported the same skin temperatures as comfortable. Although mean skin temperature is significant, the temperature of the extremities is more frequently the critical factor for comfort in the cold. Consistent with this, one of the first responses to cold exposure is vasoconstriction, which reduces circulatory heat input to the hands and feet. A hand-skin temperature of 68 °F causes a report of *uncomfortably cold*; 59 °F, *extremely cold*; and 41 °F, *painful*. Identical verbal responses for the foot surface occur at approximately 2.7 to 3.5 °F warmer temperatures.

An ambient temperature of −31 °F is the lower limit for useful outdoor activity, even with adequate insulative clothing. At −58 °F, almost all outdoor effort becomes exceedingly difficult; even with appropriate protective equipment, only limited exposure is possible. Reported exposures of 30 min at −103 °F have occurred in the Antarctic without injury.

In response to extreme heat loss, maximal heat production becomes very important. When the less efficient vasoconstriction cannot prevent body heat loss, shivering is an automatic, more efficient defense against cold. This can be triggered by low deep body temperature, low skin temperature, rapid change of skin temperature, or some combination of all three. Shivering is usually preceded by an imperceptible increase in muscle tension and by noticeable gooseflesh produced by muscle contraction in the skin. It begins slowly in small muscle groups, initially increasing total heat production by 1.5 to 2 times resting levels. As body cooling increases, the reaction spreads to additional body segments. Ultimately violent, whole body shivering causes maximum heat production of about 6 times resting levels, rendering the individual totally ineffective.

Given sufficient cold exposure, the body undergoes changes that indicate cold acclimatization. These physiological changes include, (1) endocrine changes (*e.g.*, sensitivity to norepinephrine), causing nonshivering heat production by metabolism of free fatty acids released from adipose tissue; (2) improved circulatory heat flow to skin, causing an overall sensation of greater comfort; and (3) improved circulatory heat flow to the extremities, reducing the risk of injury and permitting activities at what ordinarily would be severely uncomfortable temperatures in the extremities. Generally, these physiological changes are minor and are induced only by repeated extreme exposures. Nonphysiological factors, including training, experience, and selection of adequate protective clothing, are more useful and may be safer than dependence on physiological changes.

The caloric requirement for adequately clothed subjects in extreme cold is only slightly greater than that for subjects living and working in temperate climates. This greater requirement results from added caloric work caused by two factors: (1) carrying the weight of heavy clothing, since energy cost is a linear function of total weight (energy cost for heavy protective footwear may

be six times that of an equivalent weight on the torso); and (2) the inefficiency of walking in snow, snowshoeing, or skiing, which can increase energy cost up to 300%.

To achieve proper protection in low temperatures, a person must either maintain high metabolic heat production by activity or reduce heat loss by controlling the body's microclimate with clothing. Other protective measures include spot radiant heating, showers of hot air for work at a fixed site, and warm air ventilated or electrically heated clothing. The extremities, such as fingers and toes, pose more of a problem than the torso because, as thin cylinders, they are particularly susceptible to heat loss and difficult to insulate without increasing the surface for heat loss. Vasoconstriction can reduce circulatory heat input to extremities by over 90%.

Although there is no ideal insulating material for protective clothing, radiation-reflective materials are promising. Insulation is primarily a function of clothing thickness; the thickness of trapped air, rather than fibers used, determines insulation effectiveness.

Protection for the respiratory tract seems unnecessary in healthy individuals, even at −49 °F. However, asthmatics or individuals with mild cardiovascular problems may benefit from a face mask that warms inspired air. Masks are unnecessary for protecting the face since heat to facial skin is not reduced by local vasoconstriction, as it is for hands. If wind chill is great, there is always a risk of cold injury caused by freezing of exposed skin. Using properly designed torso clothing, such as a parka with fur-lined hood to minimize wind penetration to the face, and 34 Btu/h of auxiliary heat to each hand and foot, inactive people can tolerate −67 °F with a 10 mph wind for more than 6 h. As long as skin temperature of fingers remains above 60 °F, manual dexterity can be maintained and useful work performed without difficulty.

SYMBOLS

A = area, ft²
- A_{cl} = surface area of clothed body
- A_D = DuBois surface area of nude body
- A_G = body surface area covered by garment
- A_r = effective radiation area of body

c_p = constant pressure specific heat, Btu/(lb · °F)
- $c_{p,a}$ = of air
- $c_{p,b}$ = of body tissue
- $c_{p,bl}$ = of blood

C_{res} = sensible heat loss due to respiration, Btu/(h · ft²)

$C+R$ = total sensible heat loss from skin, Btu/(h · ft²)

E = evaporative heat loss, Btu/(h · ft²)
- E_{dif} = due to moisture diffusion through skin
- E_{max} = maximum possible
- E_{rsw} = due to regulatory sweating
- E_{res} = due to respiration
- $E_{rsw,req}$ = required for comfort
- E_{sk} = total from skin

ERF = effective radiant field, Btu/(h · ft²)

ET* = effective temperature, °F

f_{cl} = clothing area factor, A_{cl}/A_D, dimensionless

F_{cl} = intrinsic clothing thermal efficiency, dimensionless

F_{cle} = effective clothing thermal efficiency, dimensionless

F_{pcl} = permeation efficiency, dimensionless

F_{p-j} = angle factor to person from source j, dimensionless

F_{p-N} = angle factor from person to source N, dimensionless

h = sensible heat transfer coefficient, Btu/(h · ft² · °F)
- h = total at surface
- h' = overall including clothing
- h_c = convection at surface
- h_{cc} = corrected convection at surface
- h_r = radiation

h_e = evaporative heat transfer coefficient, Btu/(h · ft² · psi)
- h_e = at surface
- h_{ec} = at surface, corrected for atmospheric pressure
- $h_{e'}$ = overall including clothing

h_{fg} = heat of vaporization of water, Btu/lb

i = vapor permeation efficiency, dimensionless
- i_a = air layer
- i_{cl} = clothing
- i_m = total

I = thermal resistance in clo units, clo

All subscripts given for symbol R apply to symbol I

J = irradiance, Btu/(h · ft²)

k = thermal conductivity of body tissue, Btu/(h · ft · °F)

K = effective conductance between core and skin, Btu/(h · ft² · °F)

l = height, ft

L = thermal load on body, Btu/(h · ft²)

LR = Lewis ratio, °F/psi

m = body mass, lb

m_{ge} = mass to gas exchange, lb

$\dot{m}$ = mass flow, lb/(h · ft²)
- $\dot{m}_{bl}$ = blood circulation between core and skin
- $\dot{m}_{rsw}$ = rate of regulatory sweat generation

$\dot{m}_{res}$ = pulmonary ventilation rate flow, lb/h

M = metabolic heat production, Btu/(h · ft²)
- M = total
- M' = net
- M_{act} = due to activity
- M_{shiv} = due to shivering

p = water vapor pressure, psi
- p_a = in ambient air
- $p_{ET^*,s}$ = saturated at ET*
- $p_{oh,s}$ = saturated at t_{oh}
- $p_{sk,s}$ = saturated at t_{sk}

p_t = atmospheric pressure, psi

Q = heat flow, Btu/(h · ft²)
- Q_{crsk} = from core to skin
- Q_{res} = total due to respiration
- Q_{sk} = total from the skin

R = thermal insulation, h · ft² · °F/Btu
- R_a = air layer on nude skin
- $R_{a,cl}$ = air layer at outer surface
- R_{cl} = clothing
- R_{cle} = change due to clothing
- R_t = total

R_e = evaporative resistance, h · ft² · psi/Btu
- $R_{e,cl}$ = clothing
- $R_{e,t}$ = total

RQ = respiratory quotient, dimensionless

S = heat storage, Btu/(h · ft²)
- S_{cr} = in core compartment
- S_{sk} = in skin compartment

SET* = standard effective temperature, °F

t = temperature, °F
- t_a = ambient air
- t_b = average of body
  - $t_{b,c}$ = lower limit for evaporative regulation zone
  - $t_{b,h}$ = upper limit for evaporative regulation zone
  - $t_{b,n}$ = at neutrality
- t_{com} = combined temperature
- t_{cl} = clothing surface
- t_{cr} = core
  - $t_{cr,n}$ = at neutrality

t_{db} = dry bulb
$t_{eq,wc}$ = equivalent wind chill temperature
t_{ex} = of exhaled air
t_g = globe
t_N = of surface N
t_{nwb} = naturally ventilated wet bulb
t_o = operative
t_{pr} = plane radiant
t_s = surface
t_{sf} = final skin
t_{si} = initial skin
t_{sk} = skin
$t_{sk,n}$ = at neutrality
$t_{sk,req}$ = required for comfort
$\bar{t}_r$ = mean radiant
T = absolute temperature, °R
All subscripts that apply to symbol t may apply to symbol T.
Tu = turbulence intensity, %
V = air velocity, fpm
V_{CO_2} = volume rate of CO_2 produced, ft^3/h
V_{O_2} = volume rate of O_2 consumed, ft^3/h
w = skin wettedness, dimensionless
w_{rsw} = required to evaporate regulatory sweat
W = external work accomplished, $Btu/(h \cdot ft^2)$
W_a = humidity ratio of ambient air, lb H_2O/lb d.a.
W_{ex} = humidity ratio of exhaled air, lb H_2O/lb d.a.
α = fraction of total body mass concentrated in skin compartment, dimensionless
σ = Stefan-Boltzman = n constant, $Btu/(h \cdot ft^2 \cdot °R^4)$
ϵ = emissivity, dimensionless
η = evaporative efficiency, dimensionless
ρ = density, lb/ft^3
θ = time, h

CHAPTER 9

ENVIRONMENTAL CONTROL FOR ANIMALS AND PLANTS

ANIMALS 9.1
Animal Care/Welfare 9.2
Physiological Control Systems 9.2
Cattle 9.5
Sheep 9.8
Swine 9.9
Chickens 9.10
Turkeys 9.11
Laboratory Animals 9.12
PLANTS: GREENHOUSES, GROWTH CHAMBERS, AND OTHER FACILITIES 9.12
Temperature 9.13
Light and Radiation 9.15
Relative Humidity 9.17
Air Composition 9.18
Air Movement 9.18

THERMAL conditions, air quality, lighting, noise, ion concentration, and crowding are important in designing structures for animals and plants. Thermal environment influences heat dissipation by animals and chemical process rates in plants. Lighting influences photoperiodism in animals and plants, and photosynthesis and regulation in plants. Air quality, noise, ion concentrations, and crowding can affect the health and/or productivity of animals or plants. This chapter summarizes the published results from various research projects and provides a concept of the physiological factors involved in controlling the environment.

ANIMALS

Animal performance (growth, egg or milk production, wool growth, and reproduction) and their conversion of feed to useful products are closely tied to the thermal environment. For each homeothermic species, an optimum thermal environment permits necessary and desirable body functions with minimum energetic input (Figure 1A). The optimal thermal environment—in terms of an effective temperature that integrates the effects of dry-bulb temperature, humidity, air movement, and radiation—is less important to the designer than the range of conditions that provides acceptable animal performance, efficiency, well-being, and economic return for a given species. Figure 1A depicts this range as the *zone of nominal losses*, selected to limit losses in performance to a level acceptable to the livestock manager. Researchers have found that the zone of nominal losses corresponds to the welfare plateau (*i.e.*, welfare is enhanced by maintaining environmental conditions within the zone of nominal losses). Milk and egg production by mature animals also shows an optional thermal environment zone, or zone of nominal losses (Figure 2).

Developed from actual measurements of swine growth, Figure 1B shows the relationships of energy, growth, and efficiency with air temperature. In the case of growing pigs in Figure 1B, the range of temperatures from 60 to 72 °F, which includes both optimal productivity and efficiency levels, represents acceptable design conditions to achieve maximum performance and efficiency. Even beyond that temperature range, performance and efficiency do not markedly decline in the growing pig until near the lower critical temperature (LCT) or upper critical temperature (UCT), and potential performance losses within the temperature range from 50 to 76 °F may be acceptable. Response relationships, as shown in Figure 1B, allow environmental selection and design criteria to be based on penalties to performance (*i.e.*, economic costs) and animal well-being—particularly when used with climatological information to evaluate risks for a particular situation (Hahn *et al.* 1983). Choosing housing requires caution, because research indicates that factors such as group versus individual penning, feed intake, and floor type can affect the LCT by 10 °F.

The limits of acceptable values of the LCT and UCT depend on such effects as the species, breed, genetic characteristics of an individual animal's age, weight, sex, level of feeding and type of feed, prior conditioning, parasites, disease, social factors such as space allocation, lactation or gestation, and physical features of the environment. The LCT and UCT vary among individuals; data reported are for group means. As a result, the limits become statistical values based on animal population and altered by time-dependent factors.

Acceptable conditions are most commonly established based on temperature because an animal's sensible heat dissipation is largely influenced by the temperature difference between the animal's surface and ambient air. Humidity and air movement are sometimes included as modifiers for an effective temperature. This has been a logical development. Air movement is a secondary but influential factor in sensible heat dissipation. The importance of air velocities is species and age dependent (*e.g.*, swine under 8 weeks of age experience slower gains and increased disease susceptibility when air velocity is increased from 25 to 50 ft/min).

With warm or hot ambient temperature, elevated humidity can restrict performance severely. Relative humidity has little effect on the animal's heat dissipation during cold temperatures, and it is usually only moderately important to thermal comfort during moderate temperatures. (Information is limited on such interactions, as well as on the effects of barometric pressure, air composition, and thermal radiation.)

Animals housed in a closed environment alter air composition by reducing oxygen content and increasing carbon dioxide and vapor content. Decomposing waste products add methane, hydrogen sulfide, and ammonia. Animal activities and air movement add microscopic particles of dust from feed and bedding. Generally, a ventilation rate sufficient to remove water vapor adequately controls dusts and gases that can irritate the animal's respiratory tract. However, improper air movement patterns, certain waste-handling methods, and special circumstances (*e.g.*, disease outbreak) may indicate that more ventilation is necessary.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment, with cooperation of Committee SE-300 of the American Society of Agricultural Engineers.

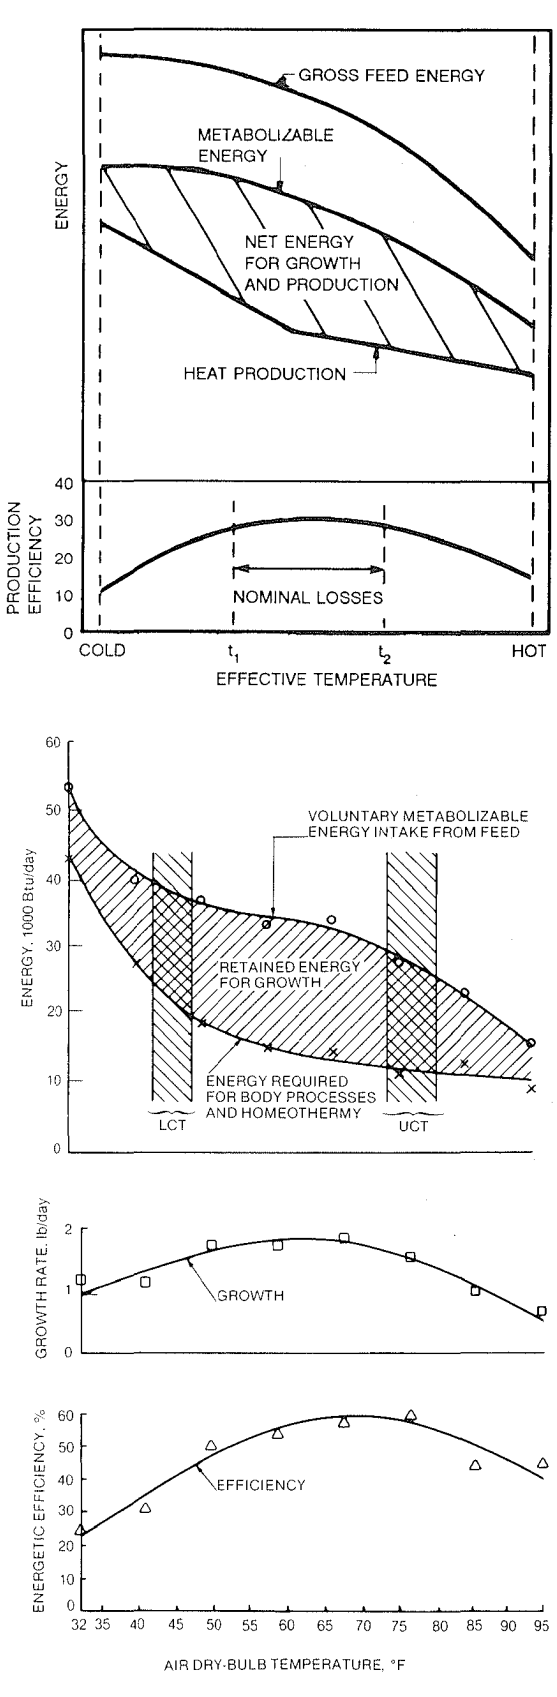

Fig. 1 Energetic and Performance Relationships Typical for Animals as Affected by Effective Environmental Temperatures
(Hahn *et al.* 1983)

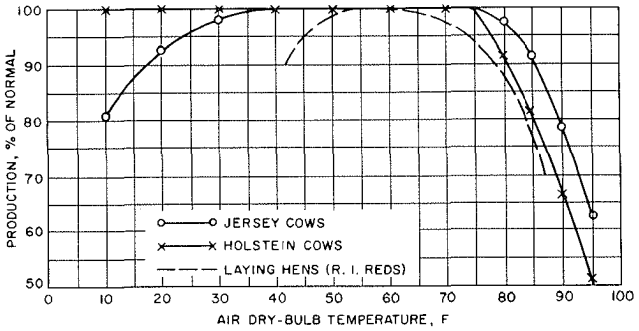

Fig. 2 Comparative Effect of Air Temperature in Mature Animal Production
(Hahn *et al.* 1983, Tienhoven *et al.* 1979)

ANIMAL CARE/WELFARE

Animal facilities that facilitate good animal care and welfare must be designed considering a wide range of environmental factors beyond thermal conditions. These include space requirements, flooring type, lighting, feed and water requirements, animal handling; and waste management. Facilities that meet animal care and welfare needs vary considerably by purpose, animal species, and geographic location. For additional information and guidelines for designing animal facilities to meet animal care and welfare needs, refer to the bibliography.

PHYSIOLOGICAL CONTROL SYSTEMS

An animal has a phenomenally stable control system (Scott *et al.* 1974, Tienhoven *et al.* 1979). Despite wide variations in environmental, nutritional, or pathological conditions, animals can control blood pressure and composition, body temperature, respiration, and cardiac output without conscious effort. Physiological control systems react to unfavorable conditions to ensure survival of the animal at the expense of production or reproduction.

One physiological control system important for air-conditioning design is the homeothermic system—the means by which an animal adapts to its thermal environment. The animal strives to control body temperature by adjusting both heat production in the tissues and transfer of heat to the environment from exposed surfaces. The homeothermic system in domestic animals is a closed-loop system and can be analyzed like any closed-loop control system.

Heat Production

Heat production data have been measured for many farm animals (Yeck and Stewart 1959, Longhouse *et al.* 1960, 1968, Bond *et al.* 1959). Much of the early data were obtained for a basal condition (*i.e.*, all life processes at a minimum level). Heat production under conditions of normal metabolic activity is more useful to the engineer. Such data are now available for most farm animals (Figures 3 and 4). Where possible, the data show total or sensible and latent heat for animals fed in a typical housing situation. Thus, the sensible heat used to evaporate urine moisture (assuming no other moisture) appears as latent heat. For design purposes, such data are better reflections of total heat partitioning than metabolic heat production obtained by calorimetry. Scott *et al.* (1983) provide additional information on specific situations.

The rate of heat production is primarily a function of temperature, animal species, and animal size (Brody *et al.* 1945). Heat production varies diurnally, depending on animal activity and eating times, and may change dramatically under special circum-

stances (*e.g.*, when animals are disease-stressed). Building type and waste-handling system can affect the conversion of sensible to latent heat by more than 50%. Therefore, the ranges of ventilation require careful analysis.

Heat Transfer to Environment

An animal can control, to some extent, the amount of heat transferred from its body by chemical and physical regulations. In a cold environment, the animal's metabolism increases, which increases the amount of heat production, offsetting heat transfer to the environment (Brody 1945). (The principal result of such chemical regulation is inefficient feed utilization.) Physical regulation is also used in a cold environment; blood circulation to subcutaneous capillaries decreases, hair or feathers are erected, and animals huddle together in an attempt to reduce sensible heat loss. In a hot environment, opposite physical and physiological responses generally occur to enable transfer to the environment of heat associated with necessary and productive life processes. In addition, as sensible heat dissipation becomes more difficult, evaporative heat loss increases and air moisture content becomes a factor in heat loss. Since the production of heat is a necessary by-product of growth and useful production, environmental limits to dissipating this heat cause a decrease in feed consumption and subsequent decrease in growth and production.

Most sensible heat of domestic animals is dissipated through the skin. Birds, sheep, and swine transfer most of their latent heat through the respiratory tract; cattle and horses transfer most of their latent heat through the skin. Blood transfers the heat produced by metabolism to the skin or to the lung surfaces, where it is dissipated by evaporation from the mucous layer coating the inside of the alveoli. Inspired air reaching the alveoli is heated almost to body temperature and may become nearly saturated with moisture. Expired air may not be saturated at body temperature— especially during periods of heat stress—because it is a combination of air, some of which has not reached deeply into the lungs. Minor amounts of heat are also transferred by ingestion of feed and water and through excretion.

Design factors affecting animal heat loss are (1) air temperature; (2) air vapor pressure; (3) air movement; (4) configuration, emissivity, absorptivity, and surface temperature of the surrounding shelter; and (5) temperature and conductivity of surfaces (*e.g.*, floors with which the animal may be in contact).

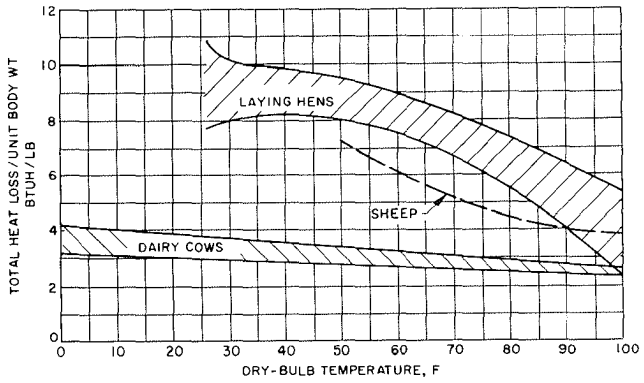

Fig. 3 Comparative Heat Loss of Mature, Producing Animals
(Tienhoven *et al.* 1979)

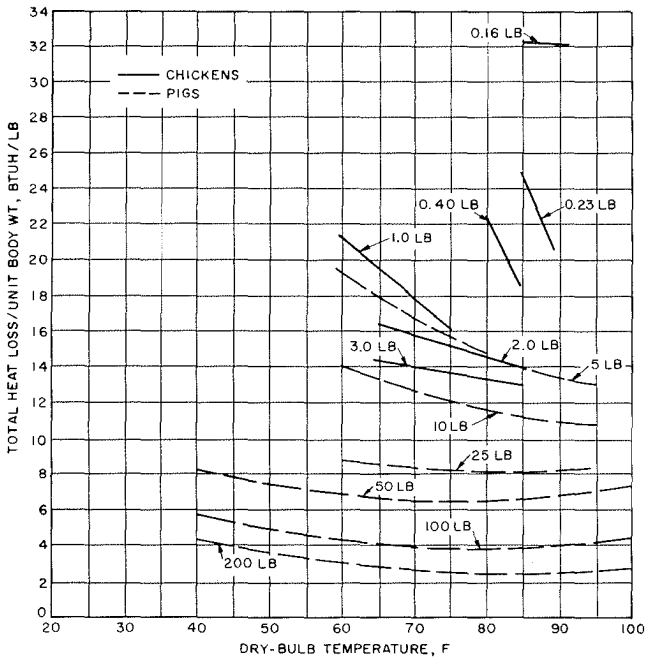

Fig. 4 Comparative Heat Loss of Growing Animals
(Bond *et al.* 1959)

Cyclic Conditions

The physiologic sensing elements respond both to environmental conditions and to changes in those conditions. Cycles of temperature, pressure, light, nutrients, parasites, magnetic fields, ionization, and other factors frequently occur with little engineering control.

Light is perhaps the earliest discovered and most important controlled environmental variable affecting reproductive processes (Farner 1961). However, the effects vary widely among animal species and age. Some animals grow and remain healthy with or without light (*e.g.*, growing swine), while for others, lighting management is important. Studies have shown that (1) short photoperiods induce or accelerate estrus development in sheep; (2) day length affects semen production in sheep and horses (Farner 1961); (3) continuous white incandescent light during incubation of White Leghorn eggs caused eggs to hatch from 16 to 24 h earlier than eggs incubated in darkness (Shutze *et al.* 1962); and (4) red, yellow, or blue lights gave comparable results. Use of lights for only one of the three weeks also reduced the time required for hatching, but differences were not as marked. Percent hatchability was not affected by lighting treatments.

Light is used to delay sexual maturity in hens, which enhances subsequent production. This is done by gradually decreasing day length from hatching to 22 weeks of age or by abruptly decreasing day length to 9 h at 14 to 16 weeks of age. If pullets have previously been exposed to an increasing day length, the change should take place at 14 weeks of age; if exposed to a constant or decreasing schedule, a change at 16 weeks is adequate. Light intensities of 1 to 2 footcandles measured at bird height were adequate in all cases. Light can then be abruptly increased at 21 weeks of age to 14 or 16 h of light. The economic value of increasing day length beyond 14 h in a windowless poultry house, and 16 h in an open poultry house, has not been proved. Recently, photoperiods such as 8 h of light (L), 10 h of darkness (D), 2 L and 4 D, and other cycles have improved feed utilization, egg production, and poultry growth (Buckland 1975).

Continuous light from hatching through 20 to 21 weeks of age markedly depressed subsequent egg production and caused a severe eye abnormality, but did not depress egg mass. (Light intensity was 1 to 3 footcandles, measured at bird height.)

Temperature cycles have been studied in cattle (Brody *et al.* 1955, Kibler and Brody 1956), swine (Bond *et al.* 1963, Nienaber *et al.* 1987), and poultry (Squibb 1959). The results differ somewhat

among animals. Heat loss from cattle and swine can usually be calculated from average daily environmental temperatures with sufficient accuracy for design load calculation.

Productivity is only slightly different for averaged temperatures when cyclic conditions with a range less than 20 °F are experienced (Squibb 1959). Above that range, productivity is depressed below that expected from the averaged temperature as determined in constant temperature tests, but under diurnally varying air conditions (68 to 77 °F temperature and widely varying humidities), near-normal egg production is maintained.

Air Composition and Contaminants

The major contaminants in livestock housing are (1) respirable dusts from feed; manure; and animal skins, hair, and feathers; (2) microbes, both pathogenic and nonpathogenic, hosted in the respiratory tracts or animal wastes; and (3) gases of many types. Respirable dust particles have diameters between approximately 0.5 and 5 μm. The gases of most concern are ammonia, hydrogen sulfide, and carbon monoxide.

Dust is generated primarily by increases in animal activity and air movement causing reentrainment of settled dust. Airborne microbes in a calf nursery are generated through defecation, urination, and coughing by the calves (Van Wicklen and Albright 1987). Gases are produced from the metabolic processes of animals and from the anaerobic microbial degradation of wastes (Muehling 1970).

Contaminants are a concern because they predispose animals to disease and poorer performance and affect operator health. Common agricultural animals can tolerate higher levels of most air contaminants than most humans without adverse health effects. However, animals experiencing stress (*e.g.*, newborns, hot or cold, nutritionally limited, and sick animals) are more sensitive, and the presence of low levels of contaminants can have adverse effects on them.

The Occupational Safety and Health Administration has established minimum standards for exposure to air contaminants that are indicators of the maximum safe level for the operators (Table 1) (OSHA 1985). These are time-dependent—people experiencing contaminants for less than a 40-h week can tolerate higher levels, while those exposed for longer periods can tolerate less. They are also additive; for example, someone exposed to 75% of the maximum dust level may be exposed to no more than 25% of the maximum for any other contaminant or combination of contaminants.

The main adverse effects of dust are that it is a carrier for microbial and contaminant gases and is an irritant that increases animal susceptibility to other contaminants. High levels of dust overload the lung clearance ability of animals. Dust may have several types of microbes that can affect animal performance. Pneumonia and other respiratory tract pathogenic bacteria can be transferred between animals from the air. Nonpathogenic bacteria may cause health problems if present in sufficient quantities to overload the body's immune system. Sick animals are more susceptible to pathogenic or nonpathogenic bacteria. Normally, when ventilation is adequate for moisture removal (Figure 5), that rate is sufficient to prevent problems due to airborne microbes; however, contaminants reach undesirable levels in confinement housing that is underventilated during cold weather (Bundy 1984). Air

(Christianson and Fehr 1983)

filtration is suggested as a means of reducing the incidence of pneumonia in an intensive calf housing (Hillman *et al.* 1992).

Airborne dust and microbes have been linked to respiratory disease in cattle, poultry, swine, horses, and laboratory animals. Infectious diseases, such as viral pneumonia and diarrhea, in calf barns have caused mortality rates between 20 and 80%, with the highest mortality occurring in enclosed barns that were underventilated during cold weather. Many respiratory diseases of poultry have been found to be transmitted via pathogenic microbes that can travel over 31 miles and remain infectious for months (Siegmund 1979). Over 1.2-million broiler chickens in Georgia were condemned postmortem at processing by inspectors during 1985 as the result of respiratory-related diseases (NASS 1986). Respiratory diseases are also costly to the swine industry—the incidence of enzootic pneumonia in pigs ranged from 30 to 75% with an estimated cost of $200-million per year (Armstrong 1982).

Gaseous ammonia is frequently a contaminant causing serious problems in swine and poultry housing. Ammonia levels of 50 ppm have been shown to reduce body mass gain rates of swine (Curtis 1983), and many researchers suspect that adverse health effects begin at levels below 25 ppm. Some physiologists and veterinary science researchers suggest that the level is between 5 and 10 ppm (Donham 1987). Ammonia at concentrations greater than 60 ppm has been implicated in reduced body weight and feed consumption, and in increased ocular and respiratory problems with broiler chickens (Carr and Nicholson 1980). Ammonia levels are influenced by the ventilation rate, sanitation practices, and the waste-handling system. Ventilating for moisture control is usually adequate to control ammonia below 10 mg in buildings sanitized monthly, where wastes are not allowed to accumulate for more than one month and where manure solids are covered by water.

Hydrogen sulfide is produced mainly from the wastes and is present at toxic levels that usually cause problems only when liquid wastes are agitated and gases from the waste handling can filter

into the animal housing area. Hydrogen sulfide production can rise to lethal levels when manure in a pit below the animals is agitated, so extra precautions are necessary to ensure that ventilation is sufficient to remove the contamination.

Carbon monoxide is usually produced by malfunctioning heating or ventilation equipment. Many heaters are unventilated, which, when combined with the corrosive environment in livestock housing, makes this equipment susceptible to failure. Heaters should be vented to the outdoors or sensors should be installed to ensure complete combustion.

Control of air contaminants is achieved primarily through proper ventilation system design and management. High contaminant levels are a greater problem during cold weather when ventilation rates are lowered to conserve heat (Sutton *et al.* 1987). Dust removal systems such as settling systems, cyclones, fibrous filters, and electrostatic precipitation have been considered (Bundy 1986). Proper design and management of waste-handling facilities, adding fat to feed, and reducing animal and human activity have also been used to control contaminants. Respirators have been recommended to provide minimal protection for operators.

Air contaminants, the thermal environment, or both can reach lethal levels if the ventilation equipment is stopped by a power outage or equipment failure. Emergency power generation equipment should be available and alarm systems installed on important ventilation equipment.

Air Ionization

Charging the atmosphere with negative ions shows the beneficial results of reduced air contaminant levels and bacteria levels. Although negative ions kill bacteria, research results are inconclusive in determining whether the mode of action is air purification, a physiological effect on blood pH, ciliary stimulation, or a tranquilizing effect. Some researchers suggest that negative ionization is not beneficial because it can increase particle retention in the respiratory tract (Janni *et al.* 1984).

Of the various methods of ion generation investigated, those most used in the environmental field are thermionic, alpha particle emission, and high-voltage corona discharge. The latter operates more satisfactorily when discharge points are distributed over the ionized area, which helps overcome (1) ozone and nitrogen oxide production, which can occur when sufficient ion production for a large space is generated at one source and (2) much of the neutralizing effect caused by ions attached to dust particles, due to the short life of air ions. The entire enclosure acts as a low-level air cleaner because of electrostatic dust precipitation to grounded surfaces. Air bacteria counts drop about 50%, and even further reduction may be possible.

Interactive Stressors

Thermal (air temperature, air humidity, air velocity, and surrounding surface temperatures) and air quality (relative absence of dust, microbes, and contaminant gases) are the two stressors of most concern to ventilating a livestock structure. However, health status, animal age and stage of production, nutrition, and social conditions interact with the thermal and air quality conditions to determine animal health and performance.

Whether stressors are linearly additive or otherwise is an important research area. McFarlane (1987) found that ammonia, heat, accoustic noise, disease, and beak-trimming stressor effects on chickens were linearly additive in effect on the feed efficiencies and daily gain rates.

Comparing Individual Animal and Room Heat Production Data

Liquid wastes from urine, manure, waterer spillage, and cleaning affect the sensible and latent heat fraction in a room (ASAE 1987). More water on the floors requires more thermal energy from the animals or the building heating system to evaporate the moisture. This evaporated moisture must then be removed by ventilation to prevent condensation on building surfaces and equipment and minimize adverse health effects, which can occur when humidities exceed 80%.

Floor flushing or excessive water spillage by animals can increase latent heat production by one-third from animal moisture production data, with a corresponding reduction in sensible heat production on a per-animal basis (ASAE 1987). Partially slatted floors with underfloor storage of wastes reduce the room moisture production by approximately 35%, compared to solid floor systems. Rooms with slatted floors throughout the building may have moisture production rates as much as 50% lower than solid floors. Therefore, slatted floors reduce the ventilation rate required for moisture removal, while excessive water spillage increases the moisture removal ventilation rate.

Influence of Genetic Change and Breed on Heat Production

Researchers have noted significant genetic correlations with performance. For example, swine breeds with high fat content characteristics outgained low fat content breeds, but the low fat content lines used feed more efficiently (Bereskin *et al.* 1975). Barrows (male hogs castrated before sexual maturity) ate 6% more than gilts (young sows that have not farrowed) to sustain a 7% faster growth rate.

Genetic improvements within breeds suggest that performance data should be updated periodically. Between 1962 and 1977, for example, the average gain rate for swine increased 0.15 lb per day, and feed efficiency improved 15% for Missouri hogs (Thomeczek *et al.* 1977).

CATTLE

Growth

Figure 6 shows the general growth rate for both beef and dairy breeds. Efficiency of beef calf growth is of economic importance; the dairy calf is developed for adult productive and reproductive capacity. Fattening calves and yearlings could be fed increasing amounts of grain and hay, with an expected gain of about 2 lb per day. Figure 7 shows the effect of temperature on the growth rate of several breeds of beef calves.

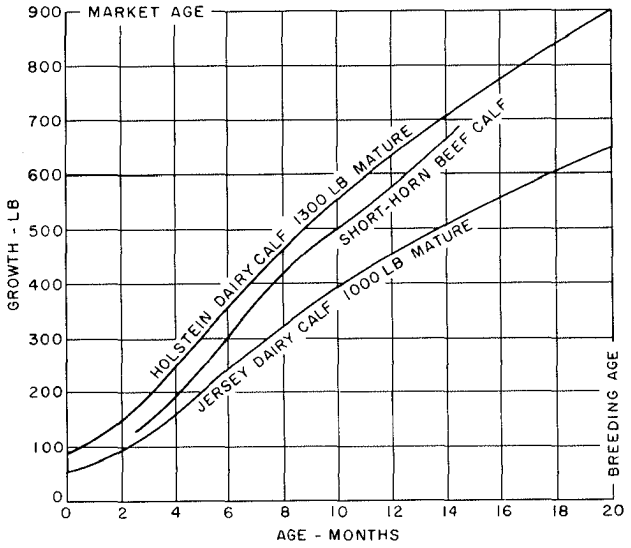

Fig. 6 General Growth Curves for Calves Fed Grain
(Johnson *et al.* 1958, Ragsdale 1960)

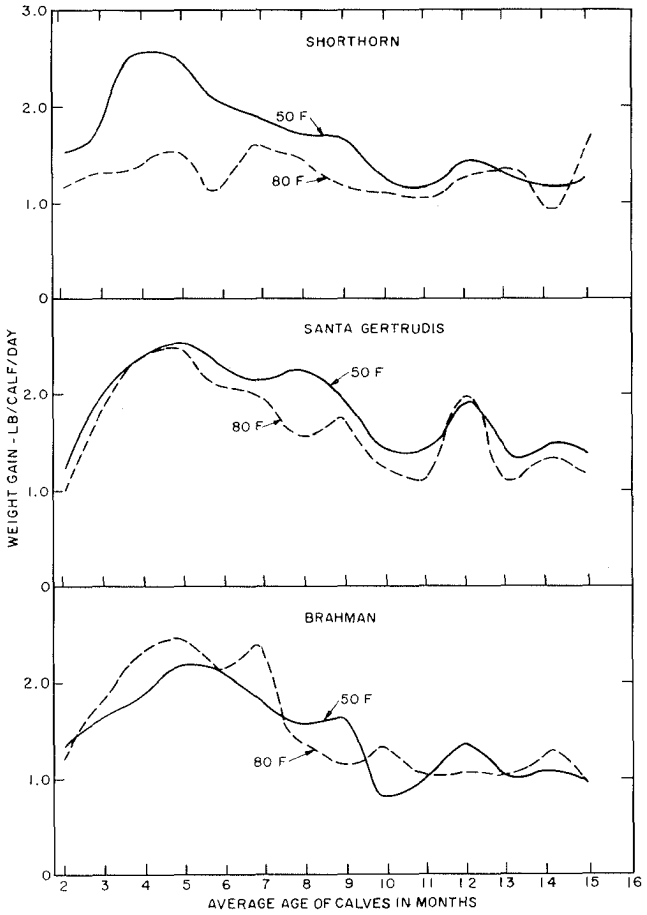

Fig. 7 Daily Weight Gain of Beef Calves
(Longhouse *et al.* 1960)

Food and energy requirements for growth can be computed by taking the difference between the energy in the available ration consumed and the energy required for maintenance and growth. Energy requirements for maintenance at an air temperature of 68 °F expressed per pound body weight has been reported to be 8.65 Btu/h (Blaxter and Wood 1951), 7.98 Btu/h (Bryant *et al.* 1967), and 8.34 Btu/h (Gebremedhin *et al.* 1983). Using 370 kcal body tissue for conversion of calories to body tissue (Brody 1945), the growth rate of a calf at 70 °F (5.38×10^{-4} lb gain per hour per pound of body weight) can be nearly 30 times that of a calf being kept at 37 °F (0.18×10^{-4} lb/h per pound of body weight) for the same investment in food (10% of body weight). Alternatively, to get the same growth rate at 37 °F as at 70 °F, the same ration must be fed at the rate of 11.6% of body weight each day, a 16% increase (Gebremedhin *et al.* 1981).

Lactation

Figure 8 illustrates the effect of high temperature on the milk production of one Holstein in a test designed to study the combined effects of temperature and humidity. The dotted line represents the normal decline in milk production (persistency) from an advancing stage of lactation.

The ideal environment for Holstein cattle should not exceed 75 °F. Jerseys are somewhat more heat tolerant, and their limit can be 80 °F (Yeck and Stewart 1959). At the lower end of the temperature scale, production decreases may be expected at 30 °F for Jerseys and below 10 °F for Holsteins and Brown Swiss.

A temperature-humidity index (THI) expresses the relationship of temperature and humidity to milk production. Temperature-humidity indexes have a greater effect on cows with a genetic potential for high milk production than for those with a lower potential (Figure 9).

Under high temperatures, a cooling system can help maintain milk production and reproductive function. In field studies conducted by Bucklin and Turner (1991) in both warm and hot, humid climates, a system providing evaporative cooling by forced air movement and direct sprinkling of lactating cows increased milk production by a range of 7 to 15% over cows not exposed to cooling.

Reproduction

Prolonged low temperatures, even those well below freezing, do not affect the reproductive performance of farm livestock, but breeding efficiency of both sexes decreases under summer conditions. Sustained temperatures above 85 °F may decrease fertility, sperm production, and semen quality of males, and increase anestrus and embryonic death in females. In bulls, temperatures above 75 °F decrease spermatogenesis, and long exposures at 85 °F or above cause temporary sterility. The extent of the reaction depends on temperature rise and exposure duration.

In females, Guazdauskas (1985) observed that conception rates decreased from a range of 40 to 80% conception in thermoneutral environments (50 to 72 °F) to a range of 10 to 51% conception in hot environments (> 81.5 °F). A cooling system involving a cooled

(Yeck and Stewart 1959)

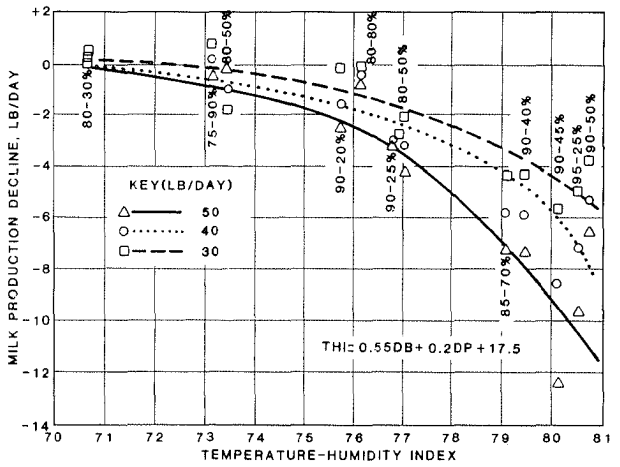

Fig. 9 Effect of Milk Production Level on Average Decline in Milk Production, versus Temperature-Humidity Index
(Johnson *et al.* 1962)

shade and artificially induced air movement increased breeding efficiency by approximately 100% in a hot climate (Wiersma and Stott 1969).

Heat and Moisture Production

Sensible and latent heat production from individual animals (Figure 10) differ from the *stable heat and moisture production* of animals (Figures 11 and 12). The data in Figures 11 and 12 were obtained while ambient conditions were at constant temperatures and relative humidities were between 55 and 70%. The effects of evaporation from feces and urine are included in these data.

The rate of cutaneous water loss is very small at colder temperatures but rises sharply above 64 °F. Cutaneous evaporation as a means of heat loss in calves becomes increasingly important as the air temperature rises above 75 °F. As the air temperature rises, the proportion of nonevaporative cooling decreases. Above 86 °F, about 80% of the heat transferred is by evaporative cooling. Gebremedhin *et al.* (1981) observed that cutaneous water loss from calves varied between 1.3×10^{-4} and 8.8×10^{-4} lb/h per pound of body weight for air temperatures between 32 and 64 °F and increases steadily beyond 64 °F (Figure 13). Water loss by respiration, the other avenue of loss, is shown in Figure 14.

SHEEP

Growth

In normal environments, an average daily gain of 0.5 lb per day can be expected of lambs marketed at 80 to 120 lb, depending on breed. Hampshires often gain more than 1 lb per day, and lambs can be fed to weigh over 200 lb while still under a year old.

Variations exist among breeds and strains of sheep in their ability to adjust to environmental changes. Temperature effects on sheep growth suggest a lower rate at elevated temperatures. A South African study shows that lack of shade in warm climates reduces growth rate. Australian studies indicate that Merino lambs survive for only about 2 h in an air temperature of 100°F.

Wool Production

The amount and quality of wool produced varies considerably among breeds, ranging from about 3 lb of poor quality wool from Dorset ewes (a breed developed primarily for mutton) to well over 10 lb of high quality fleece from dual-purpose breeds. Rambouillet, Merino, and Columbia-Southdale breeds supplied 7 lb per year, and about 4.5 lb was grown by a Hampshire, where monthly shearing increased wool production by about 1 lb per year.

Environmental factors such as photoperiod, nutritional level, and temperature also affect wool growth. Skin temperature is considered a dominant factor; high wool growth is associated with high skin temperatures. In a related study, low subcutaneous blood circulation limited wool growth. A thick fleece appears to limit radiant heat loads.

Reproduction

Sheep mate only during certain periods of the year, but they can sometimes be induced to mate outside the normal season if the natural environment is modified. Ewes may breed if exposed to an air temperature of 45°F before mating is attempted.

In studies on the effects of high temperatures on sheep reproduction, air temperature was reported to affect the spermatogenesis rate. Rams kept at 90°F environmental temperature showed a reduced rate of spermatogenesis, although a 3-week period at 70°F effected recovery to the normal rate. Later reports suggest that high air temperatures may cause lowered fertility for other reasons. Subjecting ewes to 100°F just before mating causes fertilization failure because of some form of ovum structure degeneration.

Under practical conditions, early embryonic death appears to be the greatest loss in potential offspring conceived in a high-temperature environment. Degree of susceptibility to high temperature is greatest near mating time but generally decreases as the length of time after mating increases. A temperature of 90°F and 65% rh at mating kills most embryos at an early age. The same conditions applied later in gestation do not cause death, but do cause the birth of small, weak lambs. The longer the high-temperature period, especially during the last third of gestation, the greater the number of weak lambs born. All reproductive processes appear to be more adversely affected by high air temperature when accompanied by high relative humidity.

Heat Production

Only a few heat-production tests have been conducted, mostly for correlation with other physiological data. A lamb's ability to generate heat is important because it is normally born during the most severe climatic season. One study indicated newborn lambs were limited in heat production to 30 Btu/h·lb—five times the basal level. Test conditions were from 14 to 32°F with a 12 mph wind, but lambs are capable of withstanding temperatures as low as −40°F. Table 2 provides calorimeter heat production data for sheep; while the total heat production data are reliable, the latent heat proportions do not reflect the portions of sensible heat used for water and urine evaporation from flooring and bedding.

SWINE

Ambient air temperature affects the feed conversion and daily weight of growing swine. As shown in Figure 1B, a temperature range of 60 to 72 °F produces maximum rates of gain and feed use for 155- to 220-lb hogs, while a broader range of 50 to 76 °F reduces performance only slightly. For 45- to 130-lb animals, the optimal and nominal loss ranges are about 62 to 73 °F and 55 to 76 °F, respectively (Kibler and Brady 1956). Younger animals require temperatures of 73 to 82 °F for best performance, and piglets from 3 days to 2 weeks of age should have 86 to 90 °F conditions (Hahn 1983).

Daily air temperature cycles of more than 10 °F on either side of 70 °F result in reduced daily gain by pigs and an increased feed requirement per unit of gain (Nienaber *et al.* 1987). Reasonably constant air temperatures are desirable.

The level of air temperature in which swine grow affects deposition and retention of protein (carcass quality). Lean meat formation is reportedly highest in pigs raised between 60 and 70 °F (Mount 1963). However, the ratio of protein to fat decreases at air temperatures above 59 °F.

Swine gains and feed conversion rates are highly sensitive to air velocities and, in many cases, are affected adversely at velocities as low as 50 fpm. Swine less than 8 weeks of age should not be exposed to velocities greater than 50 fpm; a velocity lower than 25 fpm is preferred when temperatures are in the recommended range. Even in hot conditions, pigs are affected adversely by air velocities greater than 200 fpm (Bond *et al.* 1965, Gunmarson *et al.* 1967, Riskowski and Bundy 1986). Feed utilization and gain are much better at low air velocities (35 fpm) than at high (300 fpm) air velocities when temperatures are optimal (Figure 15).

Reproduction

Merkle and Hazen (1967) and Heard *et al.* (1986) have shown that sows benefit from some type of cooling in hot weather. In these studies, cool, dry air was directed at the sow to relieve heat stress by increasing evaporative and convective heat dissipation. Field studies of breeding problems and resultant small litters have established that both sexes suffer losses from high temperature. Sprinkling the sow during hot weather at breeding time and shortly after resulted in more live births than with unsprinkled sows. Sprinkling boars before mating also increased the number of live births per litter. Conception rate varied from about 100% of normal at 70 °F to only 70% at 90 °F. Breeding difficulties and a decrease in live embryos were observed in tests with controlled temperatures and relative humidities (Roller and Teague 1966). In some species, spontaneous abortion under severe heat stress may save the mother's life; however, sows appear to die of heat prostration, due to extra metabolic heat generation in late pregnancy, before spontaneous abortion occurs.

Little information is available on the value of temperature control for sows during cold weather. Forcing sows to produce the necessary heat to maintain body temperature may require rigid nutritional management to avoid the animals from becoming overweight—a condition resulting in poorer conception and smaller litters.

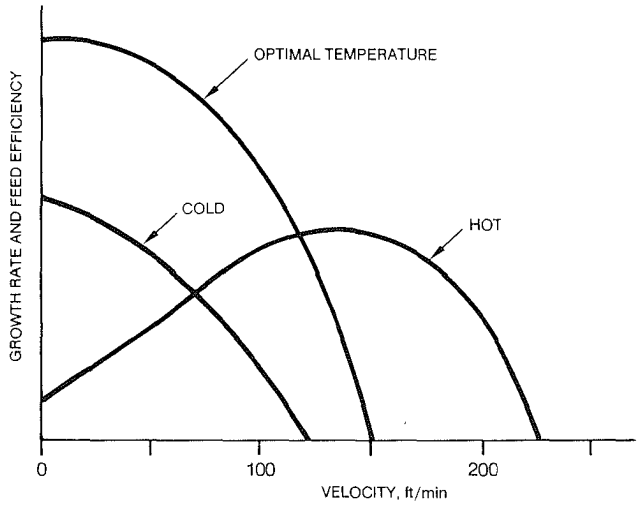

Fig. 15 Swine Response to Air Velocity
(Riskowski and Bundy 1986, Yao *et al.* 1986)

Heat and Moisture Production

Table 3 (Butchbaker and Shanklin 1964, Ota *et al.* 1982) shows direct calorimetry heat production for piglets. Figures 16 and 17 (Bond *et al.* 1959) show heat and moisture that must be accounted for in ventilating or air conditioning older swine housing for swine between 50 and 400 lb, housed at temperatures from 50 to 90 °F. These data are the sensible and latent heat levels measured in a room containing hogs. For design purposes, the room heat data reflect swine housing conditions rather than metabolic heat production from an individual animal.

The same data can be applied even where building temperatures are cycling, if the average air temperature during the cycle is used for design. The total animal heat load and the latent load that the ventilation system must remove are greater than the values in Figures 15 and 16, if the air velocity around the animals is more than about 50 fpm.

The lower critical temperature (the ambient temperature below which heat production increases) is about 77 to 86 °F for a group of newborn pigs; for a single piglet, the critical temperature is about 93 to 95 °F. As the pigs grow, the critical temperature falls—for 4.5- to 9-lb pigs, it is between 86 and 95 °F; for 9- to 18-lb pigs, between 77 and 86 °F. The floor bedding materials for growing piglets influence these critical temperatures. For a group of nine pigs averaging 88 lb, the critical temperature is 53 to 55 °F on straw, 57 to 59 °F on asphalt, and 66 to 68 °F on concrete slabs (Butchbaker and Shanklin 1964).

Table 3 Heat Production of Grouped Nursery Pigs

CHICKENS

The tremendous worldwide production of broiler chickens is a result of improvements in genetics, nutrition, and housing. Four-pound broilers are produced in about 8 weeks. Table 4 indicates the feed consumption and growth of one strain of broilers (North 1984).

Research has shown that intermittent light and darkness (photoperiod) improve growth and conserve feed and energy (McDaniel and Brewer 1975).

Supplemental heat is generally needed for newly hatched chicks. Modern broiler strains respond well to brooder temperatures of 92 °F under the heaters. Thereafter, air temperatures may be decreased at a rate of 7 °F per week until 70 °F is reached. Relative humidities of 65 to 70% promote good feathering and market-quality broilers. Air velocity effects have received limited attention. Some benefit from increased velocity (up to 500 fpm) is obtained at air temperatures from 75 to 95 °F (Drury 1966). High-velocity air, at a temperature above the feather temperatures, causes more, not less, heat stress. Observations showed that 28-day-old broilers rested in areas with airflow temperature combinations of 55 fpm at 60 °F, 100 fpm at 70 °F, and 150 fpm at 75 °F.

Source: North (1984).

Reproduction

Adverse effects of high thermal environments (above 85 °F) on egg production include fewer eggs, reduced egg weight, and thinner shells. Hens over 1 year of age are more adversely affected by high thermal environments than younger hens. Larger hens, such as Rhode Island Reds, are more adversely affected than smaller hens, such as White Leghorns. Hatchability also declines as temperatures increase. Although the fertility rate is good at 70 °F, it declines at 86 °F. Feed requirements increase markedly below 45 °F; activity and productivity decline below 32 °F. The suggested ideal environment is between 55 and 75 °F.

Increasing relative humidity above 79%, at 85 °F dry-bulb temperature, produces an increased respiration rate and drooping wings. After 7 to 10 days, acclimatization may reduce the respiration rate, but production will still be less than optimal. Generally, 70 to 75% rh is recommended to maintain conditions that are neither too dusty nor too restrictive of latent heat dissipation.

Heat and Moisture Production

Figure 18 shows the total sensible and latent heat produced by laying hens during day and night at various temperatures. Figure 19 shows the same data for chicks. Figures 20 and 21 show sensible and latent heat production for broilers grown on litter at typical stocking rates at two temperatures. The effects of heat and moisture absorption or release by the litter are included in these figures.

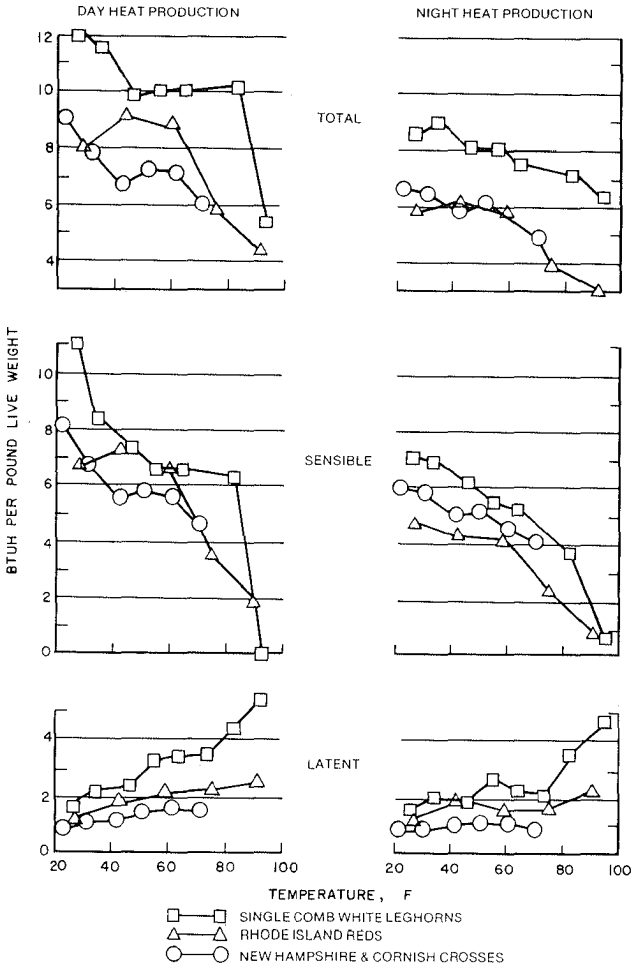

Fig. 18 Heat and Moisture Loads for Caged Laying Hens at Various Air Temperatures
(Ota and McNally 1961)

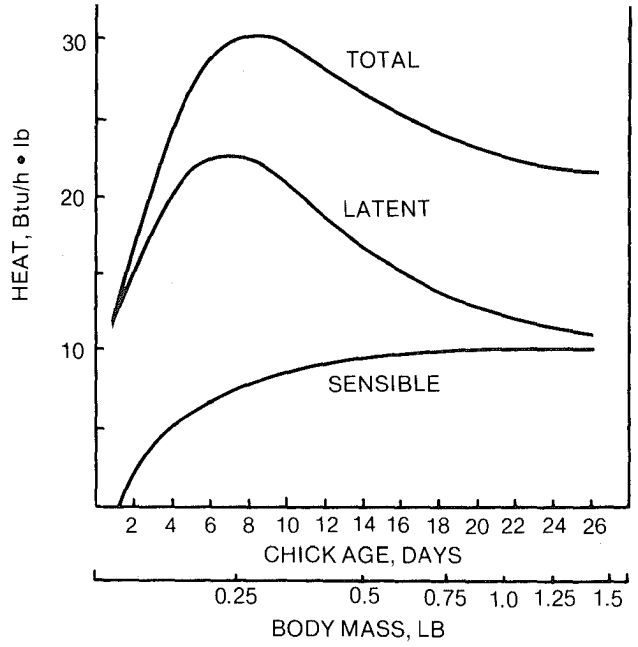

Fig. 19 Sensible, Latent, and Total Heat for Chicks Brooded on Litter
(Reece and Lott 1982)

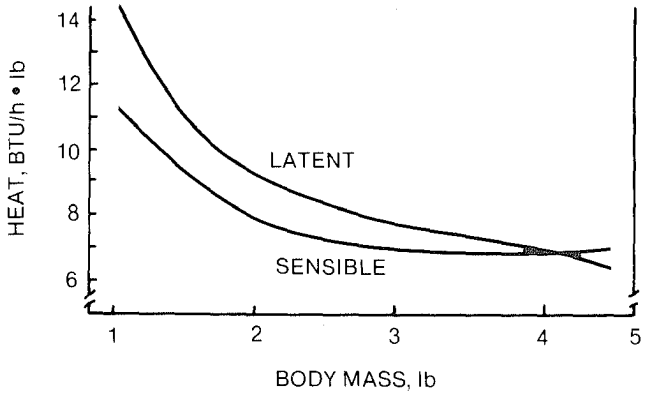

Fig. 20 Sensible and Latent Heat for Broilers Raised at 60°F on Litter
(Reece and Lott 1982)

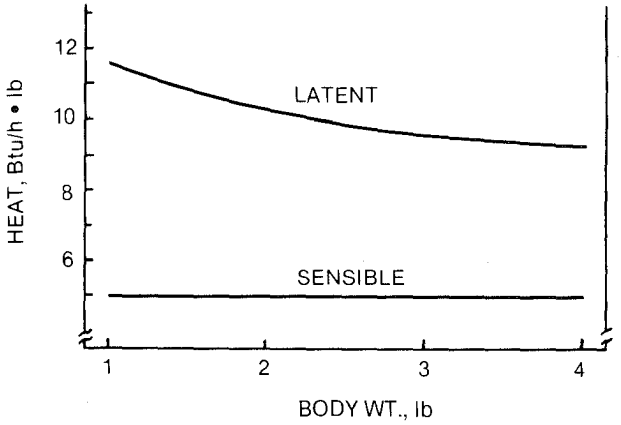

Fig. 21 Sensible and Latent Heat for Broilers Raised at 80°F on Litter
(Reece and Lott 1982)

The sensible heat loss of a layer pullet is similar to that of a broiler at the same weight (Zulovich *et al.* 1987). However, the latent heat loss of the pullet is approximately 50% that of the broiler. Layer pullets consume 20 to 25% less feed energy than broilers. Thus, the total heat production is decreased with the reduction being in latent heat loss.

TURKEYS

Growth

The turkey poult has the best rate and efficiency of gain at a brooder room temperature of 70 to 75 °F for the first 2 weeks, and 65 °F thereafter, with about 70% rh. Initial brooder temperature should be 100 °F, reduced 5 °F per week until room temperature is reached. Proper control of photoperiod stimulates the growth rate in turkeys. Table 5 shows weekly cumulative average live weight for both sexes (Sell 1990). Figure 22 provides calorimetric heat production data for medium breed turkeys.

Reproduction

Mature turkeys tolerate temperature and humidity over a range of at least 20 to 90 °F and 35 to 85% rh. Since mature birds are kept only for fertile egg production, lighting for off-season egg production becomes very important. The young stock are raised to 20 weeks on natural light. At 20 weeks, females are placed in a totally darkened pen and given 8 h per day illumination at an intensity of 2 to 5 footcandles at bird's-eye level. At 30 weeks, the sexes are mixed, and the lighting period is increased to 13 to 15 h. The breeding season then continues for 12 to 26 weeks.

Heat and Moisture Production

Table 6 gives limited calorimetric heat loss data on large breed growing turkeys (DeShazer *et al.* 1974); however, an estimate from data on heavy chickens, applied to turkeys on a live-weight basis, should be satisfactory for design purposes. The reduction in heat loss during the dark period of the day is 25% for large breeds (Buffington *et al.* 1974) and between 5 and 40% for small breeds.

The latent heat production of turkeys may be significantly higher than the 1970s data show if the growth rate or feed consumption is significantly higher in the 1990s than it was in the 1970s (see Chickens, Heat and Moisture Production).

LABORATORY ANIMALS

Significant environmental conditions for facilities that house laboratory animals include temperature, humidity, air motion, illumination, noise, and gaseous and viable particulate contaminants (Moreland 1975). Design conditions vary widely, depending on whether the animals are experiencing disease-induced stress (which alters environmental needs), subjected to test environments, or simply housed (Besch 1975, Murakami 1971, Nienaber and Hahn 1983). This fact reflects differing housing and ventilation guidelines for animals used in research (NIH 1985), compared to recommendations by the American Society of Agricultural Engineers (ASAE 1987) and Midwest Plan Service (MWPS 1983) for production agriculture. Little is known about the influence of disease on environmental requirements, animal performance, and well-being. Since significantly different conditions may exist between animal cage and animal room (macroenvironment), control of cage microenvironments is essential to ensure the animal's physiological well-being.

Heat and Moisture Production

Table 7 approximates heat released by laboratory animals at rest and during normal activity. Temperature and velocity gradient controls require low supply air-to-room air temperature differential, overhead high induction diffusion, uniform horizontal and vertical air distribution, and low return outlets. For load calculation purposes, heat gain from all laboratory animal species can be estimated (Wood *et al.* 1972, Gorton *et al.* 1976) with an acceptable level of error from:

$$ATHG = 2.5M$$

$$M = 6.6\,W^{0.75}$$

where

ATHG = average total heat gain, Btu/h per animal
M = metabolic rate of animal, Btu/h per animal
W = mass of animal, lb

Conditions in animal rooms must be maintained continuously. This requires year-round availability of refrigeration and, in some cases, dual air-conditioning facilities and emergency power for motor drives and control instruments. Chapter 14 of the 1991 ASHRAE *Handbook—Applications* has additional information on laboratory animal facilities.

PLANTS: GREENHOUSES, GROWTH CHAMBERS, AND OTHER FACILITIES

Most agronomically important plant crops are produced outdoors in favorable climates and seasons. Greenhouses and other indoor facilities are used for the out-of-season production of horticultural crops for both commercial sales and research purposes, and for producing food, floricultural, and other crops

Table 7 Heat Generated by Laboratory Animals

Animal	Weight, lb	Heat Generation, Btu/h per Animal: Basal[a]	Normally Active[b,c]: Sensible	Latent	Total
Mouse	0.046	0.66	1.11	0.54	1.65
Hamster	0.260	2.40	4.02	1.98	6.00

Chicken	4.00	18.67	12.9	21.9	34.7

[a]Based on standard metabolic rate $M = 6.6W^{0.75}$ watt per animal (Kleiber 1961) or appropriate reference (W = animal mass, lb).
[b]Referenced according to availability of heat generation data. Otherwise, heat generation is calculated on basis of ATHG = $2.5M$ (Gorton *et al.* 1976). Latent heat is assumed to be approximately 33% of total; sensible heat, 67% of total heat (Besch 1973, Woods *et al.* 1972).
[c]Data taken from Runkle (1964), Kleiber (1961), Besch (1973), Woods and Besch (1974), Woods *et al.* (1972), Bond *et al.* (1959), and Ota and McNally (1961).

in conditions that permit the highest quality by buffering the crops from the vagaries of weather. The industry that produces crops in greenhouses may be termed *controlled environment agriculture* (CEA).

Historically, many cold-climate commercial greenhouses were operated only from late winter into early summer, and during autumn. Greenhouses were too warm during midsummer; during winter in some cold-climate locations, light levels were too low and the day length inadequate for many crops. Mechanical ventilation, evaporative cooling, centralized heating systems, movable insulations, carbon dioxide enrichment, and supplemental lighting have extended the use of greenhouses to year-round cropping on a relatively large scale.

Growth chambers, growth rooms, and propagation units are environmentally controlled spaces used for either research or commercial crop production. Environmentally controlled chambers may include highly sophisticated facilities used for micropropagation (*e.g.*, tissue culture), or may be simple boxes in which air temperature and lights are controlled. Indoor facilities having controlled temperature and humidity environments may be used as warehouses to hold plants and plant products prior to commercial sale. Often these are simple refrigerated storage rooms or chambers.

Primary atmospheric requirements for plant production include: (1) favorable temperatures, (2) adequate light intensity and suitable radiation spectrum, and (3) favorable air composition and circulation. Engineering design to meet these requirements typically is based on steady-state assumptions. The thermal and ventilation time constants of most greenhouses are sufficiently short that transient conditions are seldom considered.

TEMPERATURE

Plant Requirements

Leaf and root temperatures are dominant environmental factors for plant growth and flowering. Factors in the energy balance of a plant canopy include air temperature, relative humidity, air movement, thermal radiation exchange, and convective exchange coefficients for sensible and latent heat. Therefore, leaf temperature is affected by environmental influences such as the type of heating and ventilating systems, supplemental lighting, light transmittance characteristics of the greenhouse cover, misting or evaporative cooling, location of the leaf on the plant, and the geometry of the surrounding leaf canopy.

Most information on plant responses to temperature is based on air temperature rather than plant temperature. Leaf temperature is difficult to measure, and one or several leaves represent neither the average nor the extreme temperatures of the plant. Since plants cannot actively regulate their cell and tissue temperatures in response to changing ambient conditions (passive regulation by opening and closing leaf stomata, which controls evapotranspiration, provides a small degree of control), their leaves and stems are usually within a few degrees of the surrounding air temperature (above during times of solar insolation, below at other times due to thermal reradiation and evapotranspiration).

All plants have minimum, optimum, and maximum temperatures for growth. Optimum temperature depends on the physiological process desired. Thermoperiodic species have different optimum day and night temperatures for each stage of growth, and each stage of plant growth may have its own unique optimum temperature influenced by radiant flux density, the ambient carbon dioxide level, and water and nutrient availability.

Historically, plants have been grown with night temperatures lower than day temperatures. In practice, many greenhouse crops are grown at standard (blueprint) night temperatures. Day temperatures are increased from 10 to 20°F (depending on solar intensity) above night temperatures. Table 8 presents recommended ranges of night temperatures for a selection of greenhouse crops. New practices have been developed in which night temperature is kept higher than day temperature, providing a nonchemical means of height control for some plant species (*e.g.*, Easter lilies). However, thus far this technique has had limited application.

Heating Greenhouses

Heat loss from greenhouses is caused primarily by conduction through the structural cover and infiltration of outdoor air. The heating system is designed to meet the sum of the two. Perimeter heat loss is generally only a few percent of the total and is often neglected in design. When movable night insulation is used to conserve energy, heating systems are still designed to match conduction and infiltration losses without insulation because movable insulation may be opened early in the morning when outdoor air temperature is near its minimum, and excess heating capacity may be useful to melt snow in climatic regions where this occurs. Greenhouses are not designed to carry heavy snow loads.

Energy Balance

Radiation energy exchange. Solar gain can be estimated using procedures presented in Chapter 27. Not all insolation appears as sensible heat, however. As a general rule, from two-thirds to three-quarters of ambient insolation is available inside a typical commercial greenhouse. (Highly detailed models for calculating solar transmittance may be found in the literature.) If a greenhouse is filled with mature plants, approximately one-half of the available insolation (transmitted) may be converted to latent heat, one-quarter to one-third released as sensible heat, and the rest either reflected back outdoors or converted through photosynthesis (perhaps 3%).

Supplemental lighting can add significantly to the thermal load in a greenhouse. If movable night insulation is used, venting may be required during times of lighting, even during cold weather. The components of heat addition from supplemental lighting are divided between sensible and latent loads, with approximately one-quarter to one-third of the total heat load in latent form.

Reradiation heat loss from greenhouses comprises complex processes and may involve both reradiation from the structural cover and reradiation from inside the greenhouse if the cover is not thermally opaque. Glass is nearly thermally opaque, but many plastics are not. Newer plastic films may contain IR-inhibiting substances and can save a significant amount of heating energy, while adding only slightly to summer ventilation needs. Condensation on plastic films also reduces transmittance of thermal radiation, while diffusing but not seriously impairing transmittance of solar radiation. Generally, heat loss coefficients used in greenhouse design include the effects of thermal radiation exchange by the structural cover.

Structural heat loss. Conduction q_c plus infiltration q_i determine total heating requirements q_t. While infiltration heat loss is most accurately calculated using enthalpy differences, in practice only air temperature changes are considered, but with the apparent specific heat of air adjusted upward to account for the latent heat component.

$$q_t = q_c + q_i$$
$$q_c = \Sigma UA\Delta t$$
$$q_i = c_p VN\Delta t$$

where

U = heat loss coefficient, Btu/h·ft²·°F (Table 9)
A = exposed surface area, ft²

Table 8 Recommended Night Temperatures for Greenhouse Crops

Crop Species	Night Temperatures, °F	Remarks
Aster		
Callistephus chinensis	50–55	Long days during early stages of growth
Azalea		
Rhododendron spp.	61–64	Vegetative growth and forcing specific temperatures required for flower initiation and development
Calceolaria		
C. herbeohydrida	61	Vegetative growth
	50	Flower initiation and development; initiation also occurs with long days and high temperatures if photon flux density is high
Calendula		
C. officinallis	39–45	
Calla		
Zantedeschia spp.	55–61	Decrease to 55 °F as plants bloom
Carnation		
Dianthus caryophyllus	50–52 winter 55 spring 55–61 summer	Night temperatures adjusted seasonally in relation to photon energy flux density
Chrysanthemum		
C. morifolium	61 cut flowers 63–64 pot plants	Temperatures during flower initiation especially critical; uniform initiation very important for pot mums; cultivars classified on basis of temperature for development
Cineraria		
Senecio cruentus	61	Vegetative growth
	48–52	Flower initiation and development; plant quality best at low temperatures
Crossandra		
C. infundibuliformis	75–81	Germination
	64	Growth and flowering
Cyclamen		
C. indicum	61–64	Germination
	55	Seedlings
	50–52	Growth and flowering
Foliage plants	64–70	Species differ in their temperature and radiant energy requirements
Fuchsia		
F. hydrida	52–61	Long days for flower initiation
Geranium		
Pelargonium x hortorum	55–61	61 to 64 °F for fast crops at high radiant energy flux
Gardenia		
G. grandiflora	61–63	Lower temperatures result in iron chlorosis; higher temperatures increase bud abscission
G. jasminoides	61–63	
Gloxinia		
Sinningia speciosa	64–70	Lower temperatures increase bud brittleness
Hydrangea		
H. macrophylla	55–61	Specific temperature for flower initiation and development
	61–63 (forcing)	
Iris		
I. tingitana (Wedgewood)	45–61 (forcing)	Forcing temperature 55 to 57 °F for 10/11 bulbs; 50 to 54 °F for 9/10 bulbs
Kalanchoe		
K. Blossfeldiana	61	Temperatures influence rate of flower development and incidence of powdery mildew
Lily		
Lilium longiflorum	61	Temperatures manipulated to alter rate of flower development; specific temperatures for flower initiation
Orchida		
Cattleya spp.	61	Temperature requirement of hybrids related in parental species
Orchids		
Phalaenopsis spp.	64	
Cymbidium spp.	50	
Cypripedium	50–55	
Poinsettia		
Euphorbia pulcherrima	64	Vegetative growth
	61–63	Photoperiod requirement changes with temperature; bract development influenced by temperature
Roses		
Rosa spp.	61–63	
Saintpaulia		
S. ionantha	64–70	Below 61 °F, growth is slow, hard, and brittle
Snapdragon		
Antirrhinum maias	48–50	Winter
	55–61	Spring and Fall seedlings benefit from 61 to 64 °F temperatures
Stock		
Matthiola incana	45–50	Buds fail to set if temperatures are above 64 °F for 6 h or more per day. Grown mainly as field crop in California and Arizona
Tomato	61–66	Dry temperatures from 70 to 81 °F on sunny days
Lettuce	55	63 to 64 °F on cloudy days 70 to 79 °F on sunny days
Cucumber	64	75 °F on cloudy days 81 °F on sunny days

Δt = inside minus outside air temperature, °F
c_p = volumetric specific heat of air (adjusted upward to account for latent heat component), 0.03 Btu/ft^3 · °F
V = greenhouse internal volume, ft^3
N = number of air exchanges per hour (Table 10)
Σ = summation over all exposed surfaces of the greenhouse, and perimeter heat losses may be added to conduction loss equation for completeness

When design conditions are assumed for indoor and outdoor air temperatures and air exchange rate, the resulting heat loss may be assumed equal to the peak heating requirement for the greenhouse.

No universally accepted method exists to determine season-long heating needs for greenhouses. The heating degree-day method may be applied, but heating degree-day data must be adjusted to a base lower than 65 °F because of the significant passive solar heating effect in greenhouses. The proper base must be determined locally to reflect the expected solar climate of the region and the expected greenhouse operating temperature. These difficulties often lead designers to obtain season-long heating data from comparable, existing greenhouses in the region, and apply them to new designs.

LIGHT AND RADIATION

Plant Requirements

Light (400 to 700 nm) is essential for plant vegetative growth and reproduction (Figures 23 and 24). Intensity integrated over time provides the energy for growth and development, while duration (either long or short, depending on species) may be essential for certain physiological processes such as flowering. High light intensity may exceed the ability of individual leaves to photosynthesize. However, if there is a dense canopy, excess light may be beneficial to lower leaves even when upper leaves are light saturated. The intensity at which light saturates a leaf depends on various environmental factors, such as the concentration of carbon dioxide in the ambient air, as well as biological factors (Figure 25).

Table 9 Suggested Heat Transmission Coefficients

		U, Btu/h · ft^2 · °F
Glass		
	Single-glazing	1.13
	Double-glazing	0.70
	Insulating	Manufacturers Data
Plastic film		
	Single film[a]	1.20
	Double film, inflated	0.70
	Single film over glass	0.85
	Double film over glass	0.60
Corrugated glass fiber		
	Reinforced panels	1.20
Plastic structured sheet[b]		
	16 mm thick	0.58
	8 mm thick	0.65
	6 mm thick	0.72

[a]Infrared barrier polyethylene films reduce heat loss; however, use this coefficient when designing heating systems because the structure could occasionally be covered with non-IR materials.
[b]Plastic structured sheets are double-walled, rigid plastic panels.

Table 10 Construction U-Value Multipliers

Metal frame and glazing system, 16 to 24 in. spacing	1.08
Metal frame and glazing system, 48 in. spacing	1.05
Fiberglass on metal frame	1.03
Film plastic on metal frame	1.02
Film or fiberglass on wood	1.00

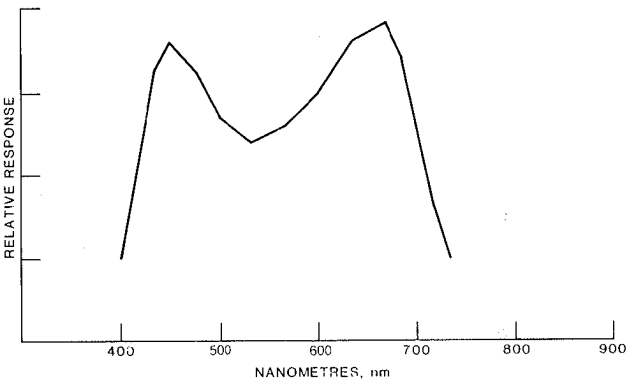

Fig. 23 Traditional Photosynthesis Action Spectra Based on Chlorophyll Absorption

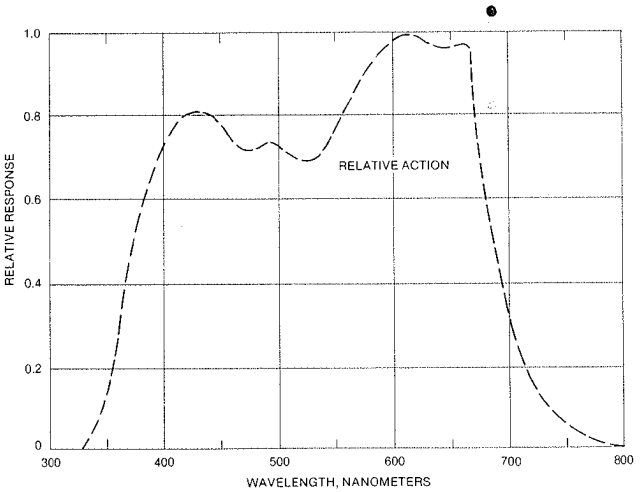

Fig. 24 Relative Photosynthetic Response

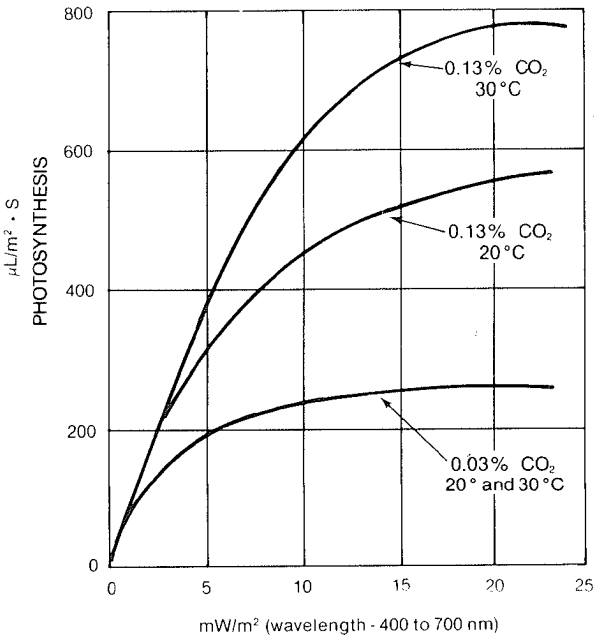

Fig. 25 Photosynthesis of Cucumber Leaf at Limiting and Saturating Carbon Dioxide Concentrations under Incandescent Light

Spectral distribution of light can affect plant development, but sunlight's spectral distribution need not be duplicated by artificial lighting to have suitable growth and development. Certain reproductive changes are initiated by red (660 nm) and far red (730 nm) light (Figure 26), and excessive ultraviolet light (290 to 390 nm) may be detrimental to growth.

Plants that respond to the durations of light and dark periods are termed photoperiodic (photoperiodic effects generally relate to flowering). Some plant species are long-day obligates, some are short-day obligates, some are day length-intermediate, and others are day-neutral. Such responses are usually (relatively) independent of light intensity. Photoperiodic effects can be initiated by very low light levels (less than 0.0929 W/ft^2), such as that provided to chrysanthemums by incandescent lights for a short period during the middle of the night to promote vegetative growth and inhibit flowering (until a suitable size has been attained) during the winter. Some plant species can tolerate continuous light, but others require some period of darkness for proper growth and development.

Sunlight is the most common source of photosynthetically active radiation (PAR, 400 to 700 nm). Although specially designed lamp sources may provide light similar to sunlight, no single source or combination of sources has spectral radiation exactly like the emission of the sun from 300 to 2700 nm. Table 11 summarizes the spectral distribution of various light sources. Three systems of measuring radiation are as follows:

1. Radiometric units (irradiance) in watts per square foot (W/ft^2), with specified wavelength intervals.
2. Quantum units as photon flux density in μmol/s·m^2 (400 to 700 nm unless otherwise specified). A mole of photons delivered in one second over a square meter may be referred to as an einstein.
3. Photometric units (illuminance) as one lumen per square meter, or lux (lx). One lumen per square foot is equivalent to one footcandle (fc).

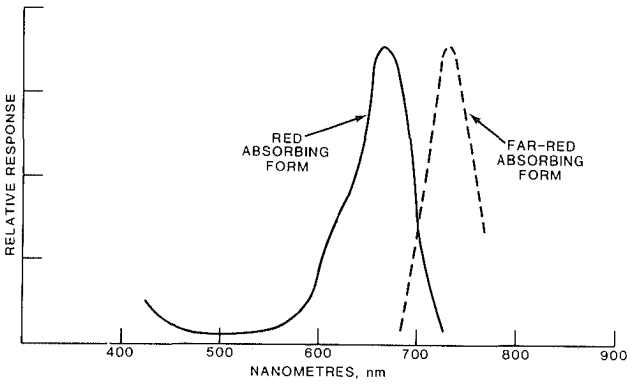

Fig. 26 Phytochrome Action Spectra

Table 11 Radiation Power Distribution of Light Sources

Light Sources	UV 300-400 nm	PAR + FR 400-850 nm	IR 850-2700 nm	Thermal 2700 + nm	Total Radiation
FCW	2	36	1	61	100
HG/DX	3	19	18	60	100
MH	4	41	8	47	100
HPS	0.4	50	12	38	100
LPS	0.1	56	3	41	100
INC	0.2	17	74	9	100
SUN	6	59	33	2	100

Note: Values are in watts per 100 W of total radiation.

Plant scientists use photosynthetic photon flux density (PPFD) in μmol/s·m^2 (400 to 700 nm). Engineering organizations and manufacturers of light sources use photometric and radiometric units. Because of the variation in spectral power distribution, conversion from one system of units to another must be made individually for each light source for the wavelength interval included (Table 12). To obtain comparable plant growth from different light sources, the same radiation levels (PAR) and red/far-red ratios must be maintained.

Radiation Levels for Plant Growth

Display 0.03 W/ft^2. For display purposes, plants can exist at an irradiance of 0.03 W/ft^2. The preferred lamp has changed with technological advances in efficiency and distribution. The emphasis, however, has always been on color rendering and the type of atmosphere created in the display space. Low-wattage incandescent and fluorescent lamps are preferred. At this irradiance, plants can be displayed (seen), but little or no significant positive effect on plants can be expected. Extended holding in such low light conditions will have a negative effect on many plant species. Timing (light-dark durations) and temperature interaction are not a concern.

Photoperiod response 0.08 W/ft^2 (4 to 6 h). For a photoperiod response, plant growth can be regulated at an irradiance of 0.08 W/ft^2 for as little time as 1 h. This irradiance is called a low light intensity system. The range of plant responses (promote or delay flowering, promote growth) that can be regulated is extensive, and this lighting is widely used by commercial growers.

Survival 0.3 W/ft^2 (8 h). Plants can survive at an irradiance of 0.3 W/ft^2 for 8 or more hours daily. This level enables many green plants to maintain their color. However, stem lengthening (etiolation) and reduction in new leaf size and thickness occur under this irradiance level. In time, the overall development of the plants falls behind that of other plants grown under higher radiation levels. Photoperiod responses do not function well at this irradiance. However, strong interactions occur between this irradiance and temperature, watering frequency, and nutrition. Cooler temperatures (less than 63 °F) help conserve previously stored material, while frequent watering and fertilization aggravate stem lengthening and senescence of older foliage.

Growth maintenance 0.8 W/ft^2 (12 h). Plants maintain growth over many months when exposed to an irradiance of 0.8 W/ft^2 of 12-h duration daily. This is the intensity at which many indoor gardeners (professional or hobbyists) grow their plants when starting them from seeds, cuttings, or meristems. Interactions with the environment (temperature, airflow, relative humidity, and pollutants) can vary among installations. Simple facilities with good air exchange and limited lamp concentration can grow a wide

Table 12 Light Conversion Factors

Light Source	Multiply W/ft^2 (400-850 nm) to Obtain: μmol/(s·ft^2) (400-700 nm)	Divide lux by Constant to Obtain: μmol/(s·ft^2) (400-700 nm)	μmol/(s·ft^2) (400-700 nm)
Sun and sky, daylight	4.57	581	388

Low-pressure sodium	4.92	1141	958

Adapted from Thimijan and Heins (1983).

range of plant species. The rate of development, particularly as the plants grow in size, can be slow compared to plants grown at higher irradiances.

Propagation 1.7 W/ft² (6 to 8 h). Plants propagate rapidly when exposed to an irradiance of 1.7 W/ft² for a minimum of 6 to 8 h daily, but they prefer 12 h. Above this level, many propagators attempt to shade their greenhouses with one or several layers of neutral filters (painted films on glazing, or movable or semipermanent plastic or other fabric shade cloth materials) to restrict light (and heat) in the propagation area.

Cuttings rooted at this intensity maintain a growth rate much like that of similar tissue on a stock plant. Stem length, branching, and leaf color, however, can be regulated by manipulating temperature, moisture, stress, and nutrients. Most plants grown for their flowers and fruits can be brought to maturity by increasing the day length to 16 to 18 h for flower initiation (or rapid growth) and then reducing the day length to 8 to 12 h for development. The growth rate, however, is relatively slow. For quickest development (leaf number, number of branches, and early flower initiation), the plants must be transferred to a higher lighting regime—2.2 to 4.6 W/ft².

Greenhouse supplemental light 2.2 W/ft² (8 to 16 h). When natural light is inadequate, it may be supplemented up to approximately 2.2 W/ft² for 8 to 16 h daily. When coupled with the ambient sunlight (shaded by clouds, greenhouse structures, and lamp fixtures), this irradiance simulates many of the growth responses and rates associated with growth chamber studies. Plants grown in greenhouses without supplemental lighting grow slower and flower later than lighted ones in cloudy regions or in northern areas during winter. Duration (in hours) and timing (day-night) of lighting is critical.

Supplemental lighting for 8 h, particularly during the day (0800 to 1600) may not be as cost-effective as lighting at night (2000 to 0400) if off-peak electric rates are available. Neither of these lighting regimes, however, is as effective as lighting for 16 h from morning to midnight.

Lighting short-day plants, such as chrysanthemums and poinsettias, is relatively inefficient because they can be lighted only during the 8- to 12-h day, followed by an obligatory 12- to 16-h daily dark period.

Growth chambers 4.6 W/ft² (8 to 24 h). Plants grow in growth chambers or growth rooms if the light irradiance is a minimum of 4.6 W/ft² for 8 to 24 h daily. This irradiance is approximately one-fourth that of outdoor sunlight. Cool, white fluorescent lamps, combined with incandescent lamps, are widely used. More recently, HID lamps have been substituted for fluorescent lamps. For consistent results, all require a barrier of glass or other material between the lamp and the plants, and a separate ventilating system to remove the heat from such enclosed spaces.

Since filters cannot remove infrared completely, chambers are difficult to standardize. This often leads to confusing information on plant growth and flowering of plants grown in greenhouses and outdoors. When the total irradiance is 4.6 W/ft² and 10 to 20% of the total radiation is provided by incandescent lamps, most kinds of plants can be grown. In typical plant forms, flowering and fruiting responses occur when the plants are subjected to the following parameters:

- Day length, 8 to 24 h
- Temperature, 50 to 95 °F
- Carbon dioxide, 300 to 2000 ppm
- Relative humidity, 20 to 80%

Photoperiod

Day length affects the performance of some plants. There are four basic day length plant groups:

1. *Short-day plants* flower only when the length of the daily light period is less than the critical number of hours. Daily light periods longer than the critical length inhibit flowering.
2. *Long-day plants* flower only when the daily light period is longer than the critical number of hours. They become dormant or remain vegetative when the daily light period is shorter than the critical length.
3. *Day length-intermediate plants* flower only within a narrow range of day length, usually between about 10 and 14 h. If the day length is shorter than the optimum day length for flowering, the plants stop growing.
4. *Day-neutral plants* continue in vegetative growth or flower regardless of the day length.

Continuous light inhibits flowering and promotes vegetative growth of short-day plants, but encourages continued vegetative growth and early flowering of long-day plants, blocks the flowering of day length-intermediate plants, and in many instances, increases the stem length of day-neutral plants. Plants vary in their responsiveness to light source, duration, and intensity. The technology that has evolved to control the photoperiod of plants is based primarily on the incandescent-filament lamp. Of all the light sources available, this lamp creates the regulating mechanism most similar to that of sunlight. This is because the red/far-red wavelength ratio of light from an incandescent lamp is similar to the ratio of sunlight.

The effectiveness for photoperiod response in plants peaks at wavelengths of 660 nm (red) and 730 nm (far-red). The relative order of activity in regulating photoperiod responses by lamp type is as follows: Incandescent (INC) > High-pressure sodium (HPS) ≫ Metal halide (MN) = Cool white fluorescent (F) = Low-pressure sodium (LPS) ≫ Clear mercury (Hg). Photoperiod lighting is always used in combination with daylight or another main light source. Short days (less than normal day length) are created in the greenhouse with opaque materials that surround the plants.

RELATIVE HUMIDITY

Relative humidity affects the rate at which plants take water up, the rate of latent heat transfer, and certain diseases. Normal plant growth generally occurs at relative humidities between 20 and 80% if the plants have a well-developed root system, although relative humidities above 40% are preferred to avoid water stress conditions.

Transpiration, the movement of water vapor and gases from the plant to its surroundings, is controlled by the plant's stomatal openings. It is a function of air velocity and the vapor pressure difference between water at saturation at the leaf temperature and the actual water vapor partial pressure in the air. Generally, as relative humidity decreases, transpiration increases. Very low relative humidities (less than 20%) can cause wilting, since evaporation losses may be higher than the plant can replace, especially when light intensity is high.

High humidity provides a good environment for pathogenic organisms. Many pathogenic spores do not germinate unless relative humidity is 96% or more and many require a film of water on the leaves. Somewhat lower relative humidities may support other pathogen growth stages.

Still air surrounding a plant may be much wetter than the general atmosphere because evapotranspiration from the leaves raises the relative humidity in interfoliage air. The lower leaves, which stay moist longer, are more susceptible to disease. The upper leaves are dried by radiation and air currents.

AIR COMPOSITION

Carbon dioxide, which comprises about 0.035% of ambient air, is essential for plant growth. There are basically three ways to obtain carbon dioxide for greenhouse enrichment: pure in solid, liquid, or gaseous form; from burning fuels such as propane, natural gas, or kerosene; and by the aerobic breakdown of organic matter. The three ways are listed in order of purity and reliability. Carbon dioxide enters plants through stomata and is converted to carbohydrates through photosynthesis. The carbon dioxide concentration in air surrounding a plant, as well as light level, affects the rate of photosynthesis. The concentration for maximum growth depends on many factors, including the stage of growth, leaf area, light intensity, temperature, and air velocity past the stomatal openings.

An important relationship exists between light level and carbon dioxide uptake (Figure 25). As light level increases, carbon dioxide concentration must increase concurrently to take maximum advantage of the greater photosynthetic potential. In plastic greenhouses, and in glass greenhouses sealed against infiltration, the carbon dioxide level can drop below 200 ppm when the weather is cold, light levels are moderate, and the greenhouse is not ventilated. Carbon dioxide enrichment just to maintain normal levels can then be beneficial. During times of high light levels, carbon dioxide enrichment gives maximum benefit from the available light and may even be economically desirable when greenhouse ventilation is modest. However, carbon dioxide concentrations above 1500 ppm are seldom recommended; levels between 800 and 1200 ppm are typically used.

The effects of enrichment are not always positive. Without proper crop management, the yield, quality, or both may decrease, and timing of crop maturity may change.

Pollutants

Plants are sensitive to atmospheric pollutants such as ethylene, ammonia, gaseous fuels, ozone, fluorides, photochemical smog, and oxidants (from nitrogen and sulfur). Pollution damage can range from small spots on leaves, to yellowing of leaves, to severe foliage burn, and, ultimately, to plant death in extreme but not rare situations. The effect occurs both outdoors and in greenhouses; however, this is more common in greenhouses, because of their closed nature. Pollutants indoors can be removed by activated charcoal filters in the ventilation system; however, these are seldom used in commercial greenhouses. Economically, the more feasible approach is to limit pollutant production within, or introduction into, the greenhouse air space.

Ethylene is produced naturally by plants and leads to flower and whole plant senescence. It is also produced by combustion of gaseous and liquid fuels and can rapidly cause plant damage. Concentrations above 0.2 ppm can have a detrimental effect on plant growth. Unvented heaters, air currents that bring vented combustion products back into the greenhouse, and burners for carbon dioxide production are common sources of ethylene injury. Liquefied carbon dioxide may be used to supplement natural levels rather than combustion, specifically to avoid introducing ethylene into the greenhouse air, but even liquefied carbon dioxide should be carefully selected to avoid residual amounts of ethylene that may be contained within it.

Nitrogen oxides, common components of air pollution, can cause serious plant damage. Greenhouse locations near highways, nearby industrial complexes, and even a truck left running for an extended time near a greenhouse air intake vent may lead to leaf damage from NO and NO_2.

Sulfur dioxide, produced by the burning of sulfur containing fuels, causes injury to many plants within a short time. Sources of sulfur dioxide may be nearby, such as an industrial area, or may be within the greenhouse complex, such as the vented combustion products from a central heating facility, combustion products from carbon dioxide burners (using kerosene as a fuel, for example), and sulfur burned for mildew control.

Ozone is widely recognized as a serious pollutant affecting the production of many agronomic crops. Although few research results exist to quantify the effect of ozone on greenhouse crops, damage is likely to occur when greenhouses are located near ozone sources.

Phenolics and certain other organic vapors are phytotoxic. Phenolics, as volatiles from certain wood preservatives (creosote and pentachlorophenol), can cause leaf and petal damage. Vapors from some paints can also be damaging. Misuse of herbicides and pesticides can lead to plant injury, either through spray drift or volatilization.

Covering and sealing greenhouses for energy conservation can increase concentrations of ethylene and other air pollutants if their sources are within the air space, since infiltration and ventilation are decreased. Sealing to reduce infiltration can also lead to rapid carbon dioxide depletion and inhibited plant growth during cold temperatures when, even with bright light, ventilation is not required.

AIR MOVEMENT

Air movement influences transpiration, evaporation, and the availability of carbon dioxide. Air speed affects the thickness of the boundary layer at the leaf surface, which in turn influences the transport resistance between the ambient air and the leaf stomatal cavities. Air speed of 100 to 150 ft/min is commonly accepted as suitable for plant growth under CEA conditions. Air speeds across the leaf of 6 to 20 ft/min are needed to facilitate carbon dioxide uptake. Air speeds above 200 ft/min can induce excessive transpiration, cause the stomatal guard cells to close, reduce carbon dioxide uptake, and inhibit plant growth. Air speeds above 1000 ft/min may cause physical damage to plants. Generally, if plants within a greenhouse move noticeably due to ventilation, air speed is excessive.

Air circulation within greenhouses may be created to reduce thermal stratification and maintain suitable levels of carbon dioxide within the leaf canopy. Horizontal air flow, produced by small propeller fans that move air around the greenhouse in a racetrack pattern, has been found to be effective. Such fans are approximately 14 in. in diameter, with approximately one-sixth horsepower (0.2 kW) motors, spaced at approximately 50-ft intervals. Total fan capacity in cfm should equal approximately 25% of the greenhouse volume in cubic feet.

CHAPTER 10

PHYSIOLOGICAL FACTORS IN DRYING AND STORING FARM CROPS

Factors Determining Safe Storage 10.1
Moisture Measurement 10.3
Prevention of Deterioration 10.6
Drying Theory 10.7
Drying Specific Crops 10.10

THIS chapter focuses on the drying and storage of grains, oilseeds, hay, cotton, and tobacco. However, the primary focus is on grains and oilseeds (collectively referred to as *grain*). Major causes of postharvest losses in these products are fungi, insects, and rodents. Substantial deterioration of grain can occur in storage. However, where the principles of good grain storage are applied, losses are minimal.

Preharvest invasion of grains by storage insects is usually not a problem in the midwestern United States. Field infestations can occur in grains when they are dried in the field at warm temperatures during harvest. Preharvest invasion by storage fungi is possible and does occur if certain weather conditions prevail when the grain is ripening. For example, preharvest invasion of corn by *Aspergillus flavus* occurs when hot weather is prevalent during grain ripening; it is, therefore, more common in the southeastern United States (McMillan *et al.* 1985). Invasion of wheat, soybeans, and corn by other fungi can occur when high ambient relative humidities prevail during grain ripening (Christensen and Meronuck 1986). However, the great majority of damage occurs during storage due to improper conditions that permit storage fungi to develop.

Deterioration from fungi during storage is prevented or minimized by (1) reducing grain moisture content below limits for growth of fungi, (2) maintaining low grain temperatures throughout the storage period to prevent fungal growth, (3) chemical treatment to prevent development of fungi or to reduce rate of fungal growth while the grain is being lowered to a safe moisture content, and (4) airtight storage in which initial microbial and seed respiration reduces the oxygen level so that further activity by potentially harmful aerobic fungi is prevented. Reduction of moisture by artificial drying is the most commonly used technique. The longer grain is stored, the lower its storage moisture should be. Some of the basic principles of grain drying and a summary of methods for predicting grain drying rate are included in the section Drying Theory.

Reduction of grain temperature by aeration is practical in temperate climates and for grains that are harvested during cooler seasons. Often, grain can be temporarily stored by using aeration to reduce its temperature to near freezing. Fans are operated when ambient temperatures are low. Basic information on aeration is summarized in the section Drying Theory. Use of refrigeration systems to reduce temperature is not usually cost-effective. Chemical treatment of grain is becoming more common and is briefly described in the section Prevention of Deterioration. When grain is placed in airtight silos, the oxygen level is rapidly reduced and carbon dioxide increases.

Although many fungi will not grow under ideal hermetic conditions in imperfectly sealed bins, some will grow initially, and this growth can reduce the feeding value of the grain for some animals. Partially emptied bins may support harmful mold growth. Sealed storage, even if successful, makes the grain unsuitable for human consumption because of yeast and bacterial growth. Airtight storage is briefly addressed in the section Factors Determining Safe Storage.

Deterioration from insects can also be prevented by a combination of reducing moistures and lowering temperatures. Lowering of temperatures is best achieved by aeration with cool ambient air during cool nights and periods of cool weather. Use of clean metal storage structures and segregation of new crop grain from carryover grain or grain contaminated with insects are important. In cases where insect infestation has already occurred, fumigation is often used to kill the insects. Prevention and control of insect infestations are addressed in the section Prevention of Deterioration.

Moisture content is the most important factor determining successful storage. Although some grains are harvested at safe storage moistures, other grains, notably corn, rice, and most oilseeds, must usually be artificially dried prior to storage. During some harvest seasons, wheat and soybeans are harvested at moistures above those safe for storage and, therefore, also require drying.

Christensen (1982), Brooker *et al.* (1974), Hall (1980), Christensen and Meronuck (1986), and Gunasekaran (1986) summarize the basic aspects of grain storage and grain drying. Chapter 22 of the 1991 ASHRAE *Handbook—Applications* covers crop drying equipment and aeration systems.

FACTORS DETERMINING SAFE STORAGE

Moisture Content

Grain is bought and sold on the basis of characteristics of representative samples. Probes or mechanical samplers, such as diverters, are used to obtain representative subsamples. Often a representative 2-lb sample must be taken from a large quantity (several tons) of grain. Parker *et al.* (1982) summarizes sampling procedures and equipment. For safe storage, it is necessary to know the range in moisture content within a given bulk and whether any of the grain in the bulk has a moisture content high enough to permit damaging fungal growth. This range can be determined by taking probe samples from different portions of the bulk. Commonly, in large quantities of bulk-stored grain, portions have moisture contents from 2 to 3% higher than the average (Brusewitz 1987). If the moisture content anywhere in the bulk is too high, fungi will grow, regardless of the average. Therefore, the moisture content of a single representative sample is not a reliable measure of storage risk or spoilage hazard. Measurement of moisture content and the precision of various moisture-measuring methods are covered in the section Moisture Measurement.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

Table 1 summarizes recommended safe storage moistures for several of the more common grains. Note that for long-term storage, lower moistures are recommended. Most storage fungi will not grow in environments where the relative humidity of the air between kernels is less than 70%. The relationship between grain moisture and the relative humidity of air between kernels is addressed in the section Equilibrium Moisture. Table 2 summarizes the minimum relative humidities and temperatures that permit the growth of common storage fungi.

Moisture Transfer

If temperatures vary within bulk-stored grain, moisture migrates from the warmer to the cooler portions. The rate of movement depends on the gradients in moisture content and temperature. Sellam and Christensen (1976) studied moisture transfer in a sample of one cubic foot of shelled corn initially at 15.5% moisture. They used heat lamps to produce a temperature differential of 18 °F along the length of a sealed plastic container 1.22 ft long. After 2 days, this gradient (approximately 15 °F/ft) caused the moisture content at the cool end to increase by 1.2% and the moisture content at the warm end to decrease by 1.1%.

Thorpe (1982) developed an equation to describe moisture transfer caused by a temperature gradient. The equation was solved numerically, and laboratory experiments of moisture transfer in wheat were successfully modeled initially at 12% moisture content. In the experiments, an 18 °F temperature gradient was developed across a column of wheat 0.66 ft thick (equivalent to a gradient of 27 °F/ft). After one month, the moisture of the warmest grain dropped to 10.6%, while the moisture of the coolest grain increased to 14%.

Smith and Sokhansanj (1990a) provided a method of approximate analysis of the energy and velocity equations of the natural convection in grain bins. They showed that for small cereals, such as wheat, the influence of convection on temperature gradients may not be significant, whereas for larger cereals, such as corn, the effect of convection is more noticeable. Smith and Sokhansanj (1990b) also showed that convection flows in a grain bin are significant if the radius of the storage bin is approximately equal to the height of the bin.

Christensen and Meronuck (1986) cite an example of heating that developed in wheat initially at 13.2% in a nonaerated bin. Specially prepared samples had been placed at various positions in the bin at the time the bin was filled. After 3 months, the grain began to heat from fungal activity. Moistures in some of the samples had increased to 18%, while in others moistures had decreased to 10%.

These examples illustrate the importance of aeration in long-term storage. Aeration is generally required for storage structures with capacities exceeding 2000 bu or 50 tons. Moisture migration can initiate fungal and insect growth, and the heat of respiration generated by these organisms accelerates their growth and leads to spoilage. Studies suggest that temperature gradients could promote spoilage of grain loaded into a ship or barge—even if the grain is initially at a uniform moisture. Most shipments do not spoil because they remain in the ship or barge for a short time and because large temperature gradients do not develop. Christensen and Meronuck (1986) report studies of grain quality in barges and ships.

Table 1 Safe Storage Moisture for Aerated Good Quality Grain
(McKenzie 1980)

Grain	Maximum Safe Moisture Content (% Wet Basis), %
Shelled corn and sorghum	
To be sold as #2 grain or equivalent by spring	15.5
To be stored up to 1 year	14
To be stored more than 1 year	13
Soybeans	
To be sold by spring	14
To be stored up to 1 year	12
Wheat	13
Small grain (oats, barley, etc.)	13
Sunflower	
To be stored up to 6 months	10
To be stored up to 1 year	8

Table 2 Approximate Temperature and Relative Humidity Requirements for Spore Germination and Growth of Fungi Common on Corn Kernels
(Stroshine *et al.* 1984)

Fungus	Minimum Percent Relative Humidity for Spore Germination[b]	Grain Moisture[a], % w.b.	Growth Temperature, °F		
			Min.	Optimum	Max.
Alternaria	91	19	25	68	97 to 104
Aspergillus glaucus	70 to 72	13.5 to 14	46	75	100
Aspergillus flavus	82	16 to 17	42 to 43	97 to 100	111 to 115
Aspergillus fumigatus	82	16 to 17	54	104 to 108	131
Cephalosporium acremonium[c]	97	22	46	75	104
Cladosporium	88	18	23	75 to 77	86 to 90
Epicoccum	91	19	25	75	82
Fusarium moniliforme	91	19	39	82	97
Fusarium graminearum, Fusarium roseum, (Gibberella zeae)	94	20 to 21	39	75	90
Mucor	91	19	25	82	97
Nigrospora oryzae[c]	91	19	39	82	90
Penicillium funiculosum[c] (field)	91	19	46	86	97
Penicillium oxalicum[c] (field)	86	17 to 18	46	86	97
Penicillium brevicompactum (storage)	81[b]	16	28	73	86
Penicillium cyclopium (storage)	81[b]	16	28	73	86
Penicillium viridicatum (storage)	81[b]	16	28	73	97

[a]Approximate corn moisture content at 77 °F, which gives an interseed relative humidity equal to the minimum at which fungus can germinate. It is probably *below* the moisture content at which the fungus would be able to compete with other fungi on grain, except for *Aspergillus glaucus*. The latter has no real competitor at 72% rh, except occasionally *Aspergillus restrictus*.

[b]Approximately 5% or more of the population can germinate at this relative humidity.

[c]Rarely found growing in stored grain, regardless of moisture and temperature.

Temperature

Most processes that cause spoilage in stored grains are accompanied by a temperature rise. Therefore, temperatures should be monitored throughout the bulk. Temperature monitoring is commonly done by attaching thermocouples to cables that extend through the bulk from the top to the bottom, with thermocouples about 6 ft apart on each cable. The cables are 20 to 25 ft apart, with usually one thermocouple for each 2500 to 4000 bu of grain. Relatively dry grain is a good insulator, so a *hot spot* can develop without being detected immediately. However, when these thermocouple spacings are used, extensive spoilage can usually be detected by a temperature rise at a nearby thermocouple. A temperature rise of even a few degrees is evidence that grain has spoiled or is spoiling. Forced aeration maintains a uniform and preferably low temperature throughout the bulk.

Most grain-infesting insects become inactive below about 55 °F. Mites remain active but cannot develop rapidly below about 40 °F. Table 2 summarizes minimum, optimum, and maximum temperatures for the growth of some common storage fungi. Storage molds grow slowly at 32 to 40 °F. However, at higher moisture contents, some species of *Penicillium* will grow when the temperature is slightly below freezing. Grains with a moisture content high enough for invasion by *Aspergillus glaucus* will deteriorate rapidly at temperatures of 75 to 85 °F but can be kept for months without damage at 40 to 50 °F. Control of fungi and insects is described further in the sections Prevention of Deterioration and Aeration of Grain.

Oxygen and Carbon Dioxide

Only a few fungi that cause stored grain deterioration can grow in an atmosphere containing only 0.1 to 0.2% oxygen or in an atmosphere containing more than 60% carbon dioxide. Some yeasts can grow in grain stored in airtight storage at moisture contents above 18 to 19% and temperatures above 40 °F, producing flavors that make the grain unsuitable as food. However, the grain remains suitable feed for cattle and swine (Hyde and Burrell 1982), and its nutritional value may be enhanced (Beeson and Perry 1958).

Airtight storage of dry grain in underground or earth-sheltered structures is increasing in popularity in many parts of the world (Dunkel 1985, Hyde and Burrell 1982). Insects present when dry grain is put into storage usually die when oxygen has been depleted and will not usually reproduce if grain is sufficiently dry and in good condition. Hyde and Burrell (1982) and Shejbal (1980) cover controlled atmosphere storage in more detail.

Insects can also be controlled in conventional storage structures by forcing carbon dioxide or other gases such as nitrogen through the grain (Jay 1980, Ripp 1984). However, the costs of controlled atmosphere storage may be high, unless the structure can be inexpensively sealed or the gases can be easily generated or purchased at a low price.

Grain Condition

Old grain or grain already invaded by storage fungi is partly deteriorated, whether or not this is evident to the naked eye. Molding occurs more rapidly in partially deteriorated grain than in sound grain when the grain is exposed to conditions favorable to mold growth. Microscopic examination, and plating techniques can often reveal the fungal infection of grain in its early stages (Christensen and Sauer 1982, Christensen and Meronuck 1986, Stroshine *et al.* 1984). Accelerated storage tests, in which samples of grain are stored at a moisture content in equilibrium with air at 80% rh and 85 °F, and examined periodically, are useful in evaluating storability. These tests enable a manager to estimate the risk of spoilage during storage and to take appropriate action.

Equilibrium Moisture

If air remains in contact with a product for sufficient time, the partial pressure of the water vapor in the air reaches an equilibrium with the partial pressure of the water vapor in the material. The relative humidity of the air at equilibrium with the material of a given moisture is the *equilibrium relative humidity*. The moisture content of the hygroscopic material in equilibrium with air of a given relative humidity is the *equilibrium moisture content* M_e.

Several theoretical, semitheoretical, and empirical models have been proposed for calculating the M_e of grains. Morey *et al.* (1978) report that the modified Henderson equation is among the best equations available:

$$M_e = \frac{1}{100}\left[\frac{\ln(1.0 - \phi)}{-K(T + C)}\right]^{1/N} \quad (1)$$

where

M_e = equilibrium moisture content, decimal, dry basis
T = temperature, °C = (°F − 32)/1.8
ϕ = relative humidity, decimal equivalent
K, N, C = empirical constant

Table 3 lists values for K, N, and C for various crops. ASAE (1990) also gives the Chung equation, another equation used to predict M_e. Figure 1, based on the Chung equation, shows equilibrium moisture content curves for shelled corn, wheat, soybeans, and rice. Note that equilibrium moisture depends highly on temperature. ASAE (1990) gives additional curves drawn from the Chung equation and tabulated experimental data. Locklair *et al.* (1957) give data for tobacco.

Both the modified Henderson and the Chung equations give only approximate values of M_e and are for desorption. When grain is rewetted after it has been dried to a low moisture, the value of M_e is generally lower for a given relative humidity. Variations of as much as 0.5 to 1.0% can result from differences in variety; maturity; and relative starch, protein, and oil content. High-temperature drying can decrease the M_e of shelled corn by 0.5 to 1.0% for a given relative humidity (Tuite and Foster 1963). Therefore, to prevent mold development, shelled corn dried at high temperatures should be stored at moistures 0.5 to 1.0% below naturally dried corn. Pfost *et al.* (1976) summarize variations in reported values of M_e for several grains.

MOISTURE MEASUREMENT

Rapid and accurate determination of moisture of grains, seeds, and other farm crops determines whether they can be safely stored. Allowable upper limits for moisture are set by the marketing

Table 3 Desorption M_e Constants for Modified Henderson Equation for Various Crops
(ASAE 1990)

Product	K	N	C
Barley	0.000022919	2.0123	195.267
Beans, edible	0.000020899	1.8812	254.230

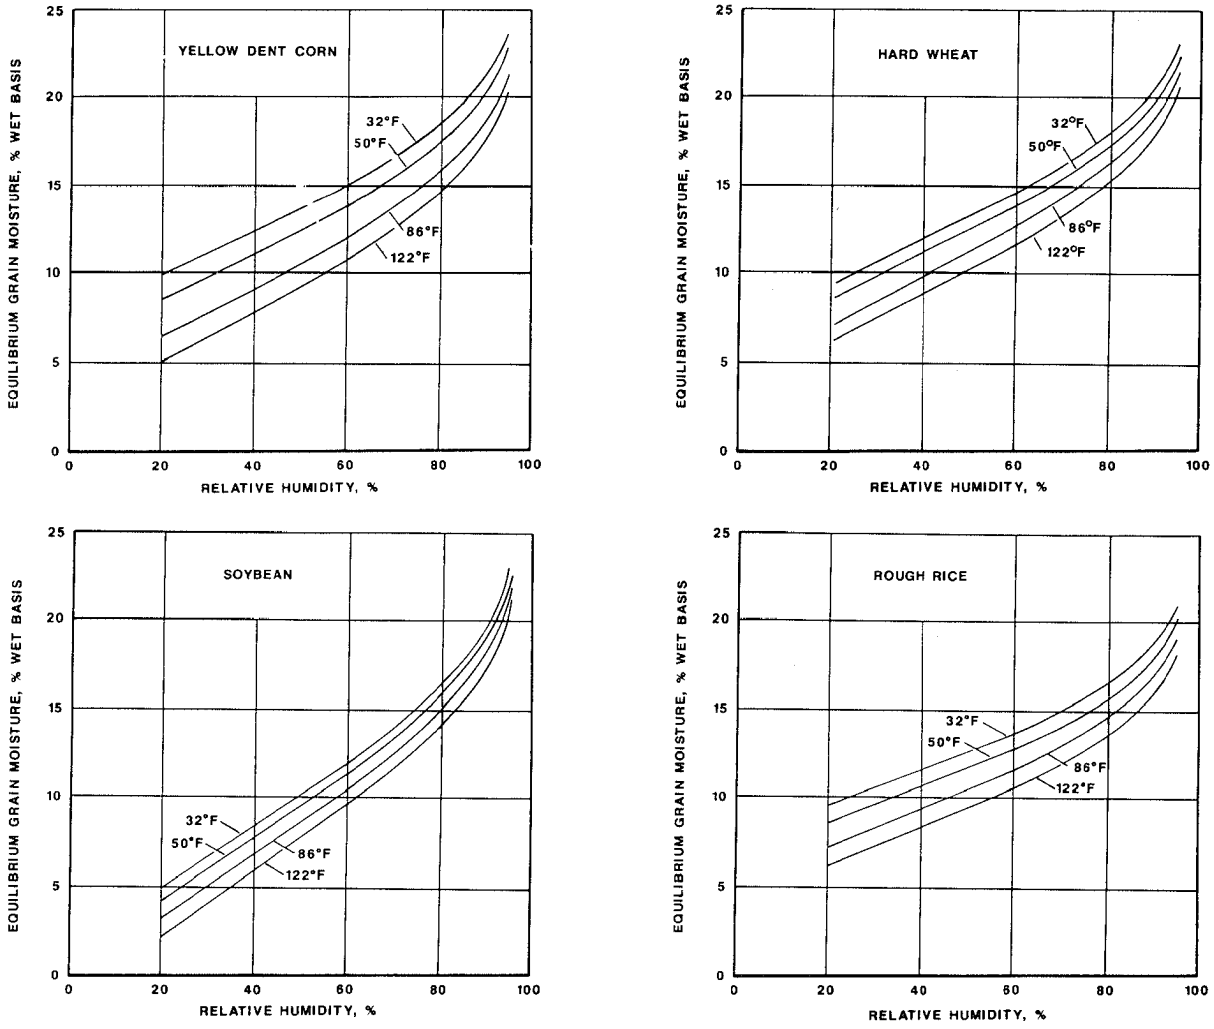

Fig. 1 Equilibrium Moisture Relationships for Certain Crops
(ASAE 1990)

system, and discounts and/or drying charges are usually imposed for higher moistures. For example, the accepted market limit on shelled corn is 15.5% moisture. If it will be stored for 4 or 5 months, it should be dried to 14.5%, and for longer storage times, 13% moisture is desirable (Table 1). Drying of the grain to moistures below the accepted market limit or the limit for safe storage moisture results in additional drying expense and may actually decrease the value of the grain.

If shelled corn is dried to 12% moisture, it becomes brittle and breaks more easily during handling. The moisture removal also reduces the total weight of grain. After drying one bushel (56.0 lbs) of shelled corn at 14% moisture to 12%, only 0.977 bushels (54.7 lbs) remain, and the market value has decreased by 2.3%. However, at high moistures, seed respiration and fungal growth can cause greater loss in dry weight.

Moisture content can be expressed on a wet or dry basis. The wet basis is used by farmers and the grain trade, while dry-basis moistures are often used by engineers and scientists to describe drying rates. Unless otherwise noted, moisture contents in this chapter are on a *wet basis* and are calculated by dividing the mass of water in the material by the total mass. The dry basis is calculated by dividing the mass of water by the mass of dry matter.

$$\% \text{ Moisture (wet basis): } M_w = 100\, W_w/(W_w + W_d) \quad (2)$$

$$\% \text{ Moisture (dry basis): } M_d = 100\, W_w/W_d \quad (3)$$

where

W_w = mass of water
W_d = mass of dry matter

Percent moisture on a wet basis M_w can be converted to percent moisture on a dry basis M_d and vice versa by the following formulas:

$$M_d = 100M_w/(100 - M_w) \quad (4)$$

$$M_w = 100M_d/(100 + M_d) \quad (5)$$

The weight change resulting from a change in moisture can be determined by assuming that the weight of dry matter is constant. The dry matter is calculated by multiplying the weight of grain by the quantity $(1 - M_w/100)$. For example, if 1000 lbs of wheat at 15% moisture is dried to 13%, the new weight W_n can be calculated by equating the amount of dry matter at 15% to that at 13% as follows:

$$1000\,(1 - 0.15) = W_n\,(1 - 0.13)$$

$$W_n = 1000\,(0.85/0.87) = 977 \text{ lbs}$$

If the final weight were known, the final moisture could be calculated by making it the unknown value in the above calculation. If two quantities of grain at differing moistures are mixed, the final moisture of the mixture can be determined by calculating the water in each, adding these together, and dividing by the total weight. The weight of water is the product of the decimal equivalent of wet-basis moisture and the weight. For example, if 500 lbs of shelled corn at 16% moisture is mixed with 1000 lbs of shelled corn at 14% moisture, the weight of water in each sample is:

$$(500 \text{ lbs})\,(0.16) = 80 \text{ lbs}$$

$$(1000 \text{ lbs})\,(0.14) = 140 \text{ lbs}$$

The moisture after mixing will be:

$$\left[\frac{80 + 140}{500 + 1000}\right](100\%) = 14.7\%$$

Methods for determining moisture content are either *direct* or *indirect*. In direct methods involving the use of an oven, water is driven from the product, and the loss in product mass caused by evaporation of the water determines the moisture content. The Karl Fischer method, a basic reference method involving a chemical reaction of water and a reagent, is also classified as a direct method.

Indirect methods, such as electric or electronic moisture meters, measure the properties of the material that are functions of the moisture content. Moisture meters are used in commercial practice, while direct methods are used in research and for calibration of the indirect methods. Christensen *et al.* (1982) summarize approved methods used in Europe and the United States.

Direct Methods

Christensen *et al.* (1982) describe fundamental or basic methods of moisture determination as (1) drying in a vacuum with a desiccant and (2) titration with a Karl Fischer reagent. It is assumed that these methods measure the true water content and can be used to verify measurements obtained with routine reference methods, including oven drying and the Brown-Duval distillation method. The Brown-Duval method, not commonly used, involves heating the grain in a special apparatus and condensing and collecting the vaporized water.

Oven techniques use either forced convection air ovens or vacuum ovens and either ground or whole kernels. Drying times and temperatures vary considerably, and the different techniques can give significantly different results. Oven techniques are used to calibrate moisture meters (see Indirect Methods). As a result, during the export of grain, the meter moisture measurements can vary between arrival and destination if the importing country uses a different standard oven technique than the exporting country.

ASAE (1990) has developed a widely used standard which recommends temperatures and heating times of various grains. Temperatures may be either 217 °F (shelled corn, soybeans, sunflower) or 266 °F (wheat, barley, onion). Heating times vary between 50 min (onion seeds) and 72 h (soybeans, shelled corn).

Grinding of samples and use of a vacuum oven reduce heating time. When initial moistures are high, two-stage methods may be used (USDA 1971). A weighed sample of whole grain is partially dried to a moisture content of 13% or below, weighed, and then ground and completely dried, as in the one-stage method. The moisture lost in both stages is used to calculate moisture content.

Indirect Methods

Electronic moisture meters are simple to operate and give readings within minutes. Therefore, they are common in commerce and the grain processing industry. Direct methods of moisture measurement are used to calibrate the meters for each type of grain. Meters are sensitive to grain temperature, and calibration must include a correction factor. The newer automatic meters or *moisture computers* sense and correct for sample temperature and print or display the corrected moisture.

Near infrared transmittance (NIR) instruments have been developed, which measure moisture, protein, starch, and oil content of ground samples (Butler 1983, Cooper 1983, Watson 1977). However, such devices are relatively expensive and require careful calibration.

Conductance-type meters measure resistance, which varies with grain moisture. The practical range of moisture content measurable by conductive meters is approximately 7 to 23%. For up to 72 h after moisture addition or removal, the moisture at the surface of the kernels differs from the moisture in the interior. Therefore, recently dried grain reads low and recently wetted grain reads high. Mixing of wet and dry grain and mixing of good grain with partially deteriorated grain also results in erroneous readings. Martin *et al.* (1986) measured the signal from the conductance-type Tag-Heppenstall meter, analyzed the standard deviation of the AC component generated during measurement, and related this to individual kernel moisture variations in mixtures of wet and dry corn.

The dielectric properties of products depend largely on moisture content. The *capacitance meter* uses this relationship by introducing grain as the dielectric in a capacitor in a high-frequency electrical circuit. Although the capacitive reactance is the primary portion of the overall impedance measured, the resistive component is also significant in many capacitance meters. At higher frequencies and in instruments with insulated electrodes, the relative effect of the resistance is reduced, which is important in reducing errors introduced by unusual product surface conditions. Capacitance meters are affected less than conductance meters by uneven moisture distribution within kernels. Sokhansanj and Nelson (1988a) showed that the capacitance-type meters give low and high readings, respectively, on recently dried or rewetted grain. The range of measurable moisture content is slightly wider than that for conductance meters.

Moisture measurement by capacitance meters is sensitive to temperature, product mass, and product density (Sokhansanj and Nelson 1988b). To reduce these sources of error, a weighed sample is introduced into the measuring cell by reproducible mechanical means. Calibration, including temperature correction, is required. At least one commercially available unit measures bulk density and corrects for this factor as well as temperature. Tests of moisture meter accuracy have been reported by Hurburgh *et al.* (1985, 1986). Accuracy of moisture readings can be improved by taking multiple samples from a grain lot and averaging the meter measurements. Equipment for continuous measurement of moisture in flowing grain is available commercially, but this equipment is not widely used in the grain trade, and its accuracy is lowered by the difficulty in controlling the density of the grain as it flows through the detector.

Equilibrium relative humidity (described in the section Equilibrium Moisture) can be used to indicate moisture content. It also indicates storability independent of the actual moisture content because the equilibrium relative humidity of the air surrounding the grain, to a large extent, determines whether mold growth can occur (see Table 2). Measurement of equilibrium relative humidity at specific points within a grain mass requires specialized sampling equipment and has been used primarily for research.

Determination of hay moisture content does not receive the consideration devoted to grains. Oven methods (ASAE 1991) are used extensively, but several conductance-type moisture meters are available for both hay and forages. The extreme variability of the moisture and density of the material tested lead to great variability

in the readings obtained. A reasonable indication of the average moisture content of a mass of hay can be obtained if many (25 or more) measurements are taken and averaged.

PREVENTION OF DETERIORATION

Fungal Growth and Mycotoxins

Fungal growth is the most important limitation on the successful storage of grain. In cases where high-temperature drying is used, it is sometimes impossible to dry grain immediately because the harvesting capacity often exceeds the capacity of the drier. Molding may occur before the grain can be dried, so the allowable storage time at the harvest moisture and temperature must be known. Low-temperature or ambient drying techniques may also be used as an alternative to high-temperature drying. In this case, wet grain is placed in the bin immediately after harvest, and the drying air is blown into a plenum in the bottom of the bin.

Drying in most farm bins begins in the lower layers and proceeds upward through the grain. The layer of grain that is drying is called the *drying zone*, and the upper boundary of the zone, where drying is just beginning, is called the *drying front*. The drying front may not reach the top of the bin for several days or weeks after drying begins. A risk associated with this type of drying is molding of the upper grain layers. Increasing the airflow increases the rate of drying but also increases costs. Therefore, the designer of low-temperature drying systems must know the maximum time that the grain at the top can be held at its harvest moisture and storage temperature before molding is significant.

In the United States, corn is one of the major crops that must be harvested above safe storage moistures. Shelled corn can be held at these higher moistures for a limited time before it must be dried. Mold growth produces carbon dioxide (CO_2). Allowable storage time at moistures above those for safe storage can be estimated by measuring CO_2 production of samples. By assuming that a simple sugar is being oxidized by microbial respiration, CO_2 production can be expressed in terms of dry matter loss in percent by mass.

Saul and Steele (1966) and Steele *et al.* (1969) studied the production of CO_2 in shelled corn, mostly on samples above 18%. Based on changes in the official grade of shelled corn, Saul and Steele (1966) established a criterion for acceptable deterioration of quality as 0.5% dry matter loss. This is equivalent to the production of 0.00735 lbs of CO_2 per pound of dry matter. Curves were developed showing grain temperature versus acceptable storage time for moistures of 18 to 30%, which are included in Chapter 22 of the 1991 ASHRAE *Handbook—Applications*. Thompson (1972) expressed Saul's data on dry matter loss per pound of dry matter as a function of moisture, time, and temperature using the following mathematical expression:

$$D_m = 1.3\left[\exp\left(\frac{0.006t}{K_m K_t}\right) - 1.0\right] + \frac{0.015t}{K_m K_t} \quad (6)$$

where

$$K_m = 0.103[\exp(455/M_d^{1.53}) - 0.00845\,M_d + 1.558] \quad (7)$$

$$K_t = A\exp(BT/60) + C\exp[0.61(T - 60)/60] \quad (8)$$

and

t = time in storage, h
T = grain temperature, °F
M_d = moisture content, % dry basis

Table 4 lists values for A, B, and C. According to Steele (1967), the damage level effect can be determined for dry matter losses (DML) of 0.1, 0.5, and 1.0% by multiplying t from Equation (6) by K_d, where K_d is calculated as follows:

$$0.1\%\ \text{DML: } K_d = 1.82\exp(-0.0143\,d) \quad (9a)$$

$$0.5\%\ \text{DML: } K_d = 2.08\exp(-0.0239\,d) \quad (9b)$$

$$1.0\%\ \text{DML: } K_d = 2.17\exp(-0.0254\,d) \quad (9c)$$

where d = mechanical damage, % by weight.

Based on a simulation, Thompson (1972) concluded that for airflow rates between 0.5 and 2.0 cfm/bu grain deterioration in the top layer during low drying is doubled when the airflow rate is halved. Thompson also concluded that weather variations during harvest and storage seasons can cause up to a two-fold difference in deterioration.

Seitz *et al.* (1982a, 1982b) found unacceptable levels of aflatoxin production prior to the time when 0.5% dry matter loss occurred. Nevertheless, the equations give approximate predictions of mold activity, and they have been used in several computer simulation studies (Pierce and Thompson 1979 and Brooker and Duggal 1982). Pierce and Thompson (1979) give recommended airflow rates for several common low-temperature drying systems and for various Midwest locations.

Acceptable dry-matter losses for wheat and barley are much lower than those for shelled corn, 0.085% and 0.104%, respectively (Brook 1987). Brook found reasonable agreement with published experimental data for the following equation (Frazer and Muir 1981) for days of allowable storage time D as a function of percent wet basis moisture M_w and temperature T in °F.

$$\log D = A + BM_w + CT + G \quad (10)$$

where $A = 6.234$, $B = -0.2118$, $C = -0.0293$, and $G = 0.937$ for $12.0 < M_w < 19.0$ and $A = 4.129$, $B = -0.0997$, $C = -0.03150$, and $G = 1.008$ for $19.0 < M_w < 24.0$.

Equation (10) was based on the development of visible mold. Brook also found that an adaptation of Saul's Equation (6) by Morey *et al.* (1981) gave reasonable results for storage time of wheat. Morey's method predicts dry matter loss by adjusting M_d for differences between corn and wheat equilibrium relative humidities.

Table 2 can be used to gain insight into the deterioration of stored grain. *Aspergillus* and *Penicillium* sp. are primarily responsible for deterioration because some of their species can grow at storage moistures and temperatures frequently encountered in commercial storage. In temperate climates, shelled corn is often harvested at relatively high moistures; during the harvest and storage season, ambient temperatures can be relatively low. Aeration of the grain during cold weather and cool nights can reduce the temperature of the grain to 40 to 60°F. This is below the optimum temperature for growth of *Aspergillus* sp. (Table 2). However, *Penicillium* sp. can still grow if grain moisture is above 16 to 17%; therefore, its growth is a persistent problem in such climates. If hot weather prevails prior to harvest, *Aspergillus*

Table 4 Constants for Dry Matter Loss of Shelled Corn [Equation (8)]

A	B	C	Temperature Range	Moisture Range, % w.b.
128.76	−4.68	0	T < 60	all moistures
32.3	−3.48	0	T ≥ 60	$M_w \leq 19$
32.3	−3.48	$\frac{M_w - 19}{100}$	T ≥ 60	$19 < M_w \leq 28$
32.3	−3.48	0.09	T ≥ 60	$M_w > 28$

flavus, which competes effectively at warmer temperatures and higher moistures, can begin to grow in the field and continue to grow in stored shelled corn. In growing seasons when shelled corn must be harvested at moistures above 22%, *Fusarium, Alternaria, Epiccocum*, and *Mucor* can compete with *Penicillium* sp.

Application of chemicals slows deterioration until grain can be either dried or fed to animals. Preservatives include propionic acid, acetic acid, isobutyric acid, butyric acid (Sauer and Burroughs 1974), a combination of sorbic acid and carbon dioxide (Danziger *et al.* 1973), ammonia (Peplinski *et al.* 1978), and sulfur dioxide (Eckhoff *et al.* 1984). Propionic acid (Hall *et al.* 1974) or propionic-acetic acid mixtures, although not extensively used, are perhaps the most popular in the United States with high-moisture corn. Acetic acid and formic acid are most popular in Europe. Grain treated with propionic acid can only be used as animal feed. Inert carriers have been used to lessen its corrosiveness.

Hertung and Drury (1974) summarize fungicidal levels needed to preserve grain at various moistures. Both ammonia (Nofsinger *et al.* 1979, Nofsinger 1982) and sulfur dioxide (Eckhoff *et al.* 1984, Tuite *et al.* 1986) treatments require considerable management. Attention must be given to uniform application of the chemicals to the entire quantity of stored grain.

Insect Infestation

Insects cause major losses of stored grain. Grain containing live insects or insect fragments in sufficient numbers is unsuitable for human food. When grain is stored for long periods (a year or more), insects can infest the grain and cause significant amounts of deterioration. Traps and chemical attractants have been developed which monitor insects in storage facilities (Barak and Harein 1982, Barak and Burkholder 1985, Burkholder and Ma 1985). Detection in samples of grain taken for grading and inspection is often difficult. Many of the insects are relatively small and can only be seen easily with a magnifying lens. Many of the insect larvae develop within the kernels and cannot be detected without the use of staining techniques or grinding of the grain sample. Infested grain mixed with good grain in marketing channels compounds the infestation problem.

Sanitation is one of the most effective methods of insect control. Cleaning of bins after removal of old-crop grain and prior to filling with new-crop grain is essential. In bins containing perforated floors, fine material that collects beneath the floors can harbor insects, which infest new-crop grain when it is added. Control by aeration is feasible in temperate climates, because insect activity is reduced greatly at temperatures below 50 °F. The effectiveness of temperature control has been documented by Bloome and Cuperus (1984) and Epperly *et al.* (1987). Chemicals have frequently been used to control live insects in grain, and methods are described by Harein (1982). Recently, thermal treatments have also been investigated (Lapp *et al.* 1986). Cotton and Wilbur (1982) summarize the types of grain insects, the ecology of insect growth, and the methods of detecting insects in samples of grain. Control of insects in farm-stored grain is detailed by Storey *et al.* (1979).

Rodents

The shift from ear corn harvesting and storage to field shelling and the introduction of metal bins have helped to reduce rodent problems. However, significant problems can arise when rodents consume grain and contaminate it with their hair and droppings. Storage structures should be made rodent-proof whenever possible. Rats can reach 13 in. up a wall, so storage structures should have concrete foundations and metal sides that resist gnawing.

In some countries, smaller on-farm storage structures are often elevated 18 in. to give protection from rodents. Double-wall construction and false ceilings should be avoided, and vents and holes should be covered with wire grates. Proper sanitation can help prevent rodent problems by eliminating areas where rodents can nest and hide. Rodents need water to survive, so elimination of available water is also effective. Techniques for killing rodents include trapping, poisoning with bait, and fumigation. Harris and Bauer (1982) address rodent problems and control in more detail.

DRYING THEORY

In ordinary applications, drying is a heat and mass transfer process that vaporizes liquid water, mixes the vapor with the drying air, and removes the vapor by carrying away the mixture mechanically. In forced convection drying, sufficient heat for vaporization of product moisture (about 1100 Btu/lb of water) comes from the sensible heat in the drying air. A few types of driers, mostly experimental types, have been developed to apply heat directly to the product by conduction, radiation, or dielectric heating.

The most common mode of drying uses the sensible heat content of the air. The method can be diagrammed on the psychrometric chart by locating the state points for the air as it is first heated from ambient temperature to plenum temperature and then exhausted from the grain. The process is assumed to be adiabatic, *i.e.*, all the sensible heat lost by the air is used for moisture vaporization and converted to latent heat of the water vapor in the drying air. Therefore, the state point of the air can be considered to move along adiabatic saturation lines on the psychrometric chart. In the simplified psychrometric chart in Figure 2, the ambient air at dry-bulb temperature t_a and dew-point temperature t_{dp} is heated to drying air temperature t_d, where it has a relative humidity ϕ_1. As the air passes through the grain, its sensible heat provides the latent heat of vaporization of the water. When the air exits from the grain, its temperature has dropped to t_e, and its relative humidity has increased to ϕ_2. The moisture gained by each pound of drying air is the difference in humidity ratio $W_2 - W_1$. If the air has sufficient contact time with the grain, the value for ϕ_2 will be the equilibrium relative humidity of the grain at that moisture and temperature t_e.

The following example illustrates a grain drying process. Shelled corn at 20% moisture is to be dried with air heated to 140 °F from an ambient temperature of 68 °F and a dew point of 50 °F. The humidity ratio of the ambient air remains constant at 0.0076 lb/lb

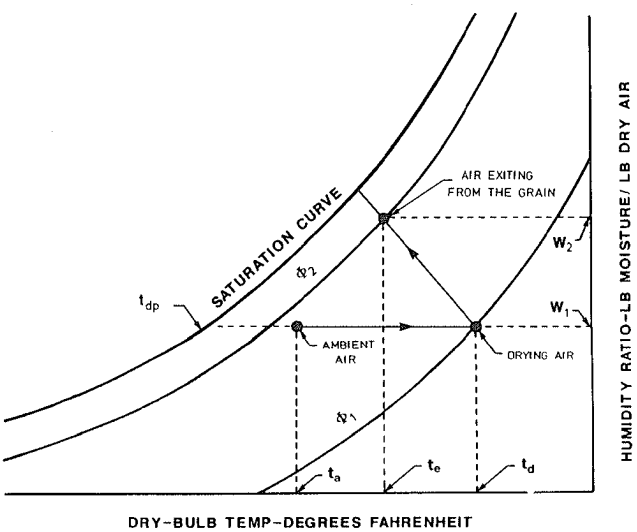

Fig. 2 Drying Process Diagrammed on Psychrometric Chart Showing Adiabatic Evaporation of Moisture from Grain

as it is heated. However, the relative humidity drops from 53% at t_a to 6% at t_d. The amount of heat added to each pound of dry air can be estimated as 18.5 Btu, the difference in enthalpy between the two state points (43 Btu/lb minus 24.5 Btu/lb). As the heated air passes through the grain and picks up moisture, it will reach 91% rh and its temperature drops to approximately 82 °F.

The exhaust air relative humidity, 91%, can be estimated by reading the equilibrium relative humidity from the curve for shelled corn shown in Figure 1. Enter the curve with a grain moisture of 20% and a temperature of 82 °F, which is slightly above the wet-bulb temperature of the drying air. As the air passes through the grain, the humidity ratio increases from 0.0076 lb/lb to 0.0215 lb/lb, and, therefore, each pound of air carries with it 0.0139 lbs (0.0215 lb/lb minus 0.0076 lb/lb) of water from the grain.

If the grain had been near 23% moisture, the exhaust air may have been nearly saturated, and the exhaust air temperature would be the wet-bulb temperature of the drying air, 79 °F. The exhaust air would have a humidity ratio of 0.0220 lb/lb, and each pound of air would carry 0.0144 lbs of water from the grain.

For a grain moisture of 16%, the equilibrium moisture content curve from Figure 1 can be used to estimate the exhaust air relative humidity as 80%. For this grain moisture, the exhaust air would have a temperature of 86 °F and a humidity ratio of 0.0210 lb/lb. Each pound of air would carry 0.0132 lbs of water from the grain.

Thin Layer Drying

A *thin layer* of grain is a layer of grain no more than several kernels deep. The ratio of grain to air is such that there is only a small change in temperature and relative humidity of the drying air when it exits the grain. The maximum rate (dM/dt) at which a thin layer of a granular hygroscopic material (such as grain) transfers moisture to or from air can be approximated by the following equation (Hukill 1947):

$$dM/dt = -C(p_g - p_a) \tag{11}$$

where

C = constant, representing vapor conductivity of kernel and surrounding air film
p_g = partial pressure of water vapor in grain
p_a = partial pressure of water vapor in drying air

If $p_g > p_a$, drying takes place. If $p_g = p_a$, moisture equilibrium exists and no moisture transfer occurs. If $p_g < p_a$, wetting occurs. The assumptions of a linear relationship between water vapor pressure and equilibrium relative humidity, and between equilibrium relative humidity and moisture content, over the range in which drying occurs, lead to the following equation:

$$dM/dt = -k(M - M_e) \tag{12}$$

where

M = moisture content (dry basis) of material at time t
M_e = equilibrium moisture content (dry basis) of material in reference to drying air
k = constant, dependent on material

The solution to this differential equation is:

$$(M - M_e)/(M_o - M_e) = \exp(-kt) \tag{13}$$

where

M_o = moisture content, dry basis, when $t = 0$

In later work (Hukill and Schmidt 1960, Troeger and Hukill 1971), Hukill recognized that Equation (13) did not describe the drying rate of grain adequately. Misra and Brooker (1980) identified the following model as more promising for shelled corn:

$$(M - M_e)/(M_o - M_e) = \exp(-Kt^N) \tag{14}$$

They give an equation for K, which is a function of drying air temperature and velocity, and another equation for N as a function of drying air relative humidity and initial grain moisture. Their equations are valid for drying air temperatures from 36 to 160 °F, drying air relative humidities of 3 to 83%, drying air velocities of 5 to 459 ft/min, and initial moistures of 18 to 60% (dry basis).

Li and Morey (1984) also fit their data to Equation (14) and found that within the limits of drying airflow rates and air relative humidities used, K and N can be expressed as functions of air temperature and initial grain moisture only. Their equations for K and N apply to air temperatures ranging from 80 to 240°F, initial grain moistures in the range of 23 to 36% dry basis, air velocities of 20 to 100 cfm/bu, and air relative humidities of 5 to 40%.

Other forms of the thin layer drying equation have also been proposed. Thompson *et al.* (1968) fit data for shelled corn to the following equation, which is applicable in the range of 140 to 300 °F:

$$t = A \ln MR + B(\ln MR)^2 \tag{15}$$

where

$A = -1.86178 + 0.00488\,T$
$B = 427.3740 \exp(-0.03301)\,T$
$MR = (M - M_e)/(M_o - M_e)$
t = time, h
T = temperature, °F

Martins and Stroshine (1987) describe the effects of hybrid and damage on the thin layer drying rate and give values for constants A and B in Equation (15) for several hybrids and damage levels.

Equations (13) through (15) do not describe the usual drying process where grain is in a deep bed and where drying air changes condition but does not necessarily reach moisture equilibrium with the grain. Those models, which are formulated using thin layer drying equations such as these, are summarized in the section Deep Bed Drying.

Results of thin layer drying tests for other grains have also been reported. Data are available for wheat (Watson and Bhargava 1974, Sokhansanj *et al.* 1984, Bruce and Sykes 1983), soybeans (Hukill and Schmidt 1960, Overhults *et al.* 1973, Sabbah *et al.* 1976), barley (O'Callaghan *et al.* 1971, Sokhansanj *et al.* 1984, Bruce 1985), sorghum (Hukill and Schmidt 1960, Paulsen and Thompson 1973), rice (Agrawal and Singh 1977, Noomhorm and Verma 1986, Banaszak and Siebenmorgen 1989), sunflower (Syarief *et al.* 1984, Li *et al.* 1987), canola (Sokhansanj *et al.* 1984), oats (Hukill and Schmidt 1960), and lentil seeds (Tang *et al.* 1989). Sokhansanj and Bruce (1987) developed more rigorous thin layer drying equations based on simultaneous heat and mass transfer through a single kernel and demonstrated that such a model accurately predicts the temperature and moisture content of the grain throughout the drying process.

Airflow Resistance

Data on resistance of grain to airflow are used for a variety of design calculations such as selecting fans, determining optimum depths for drying bins, predicting airflow paths in bins with aeration ducts, and determining the practical limitations on airflow caused by fan power requirements. For a given fan and drier or bin, airflow resistance can change with the type of grain being dried, the depth of grain, and the amount of fine material in the grain. In many grain-drying applications, such as when air is forced through a grain bin that has a uniform grain depth and a

full perforated floor, airflow is one-dimensional and the pressure drop per unit depth of grain can be assumed to be constant. The data on pressure drop per foot versus airflow in cfm per ft^2 for a number of grains and seeds were determined by Shedd (1953) and summarized by plotting them on logarithmic axes. These curves are commonly referred to as *Shedd's curves* and are included in ASAE *Standard* D272.1 (ASAE 1990). They can also be calculated from the following equation (ASAE 1990):

$$\frac{\Delta p}{L} = \frac{aQ^2}{\ln(1 + bQ)} \tag{16}$$

Table 5 summarizes the constants for Equation (16) for some of the more common grains. Constants for grass seeds and some vegetables are included in ASAE (1990).

Equation (16) gives the airflow resistance for clean, dry grain when the bin is loaded by allowing the grain to flow into the bin through a chute from a relatively low height. In the case of shelled corn, predictions of Equation (16) can be corrected for fine material using the following equation (ASAE 1990, Haque *et al.* 1978), which is valid for airflows at 15 to 40 cfm/ft^2 and on fine material fractions of 0.0 to 0.2.

$$(\Delta p/L)_{cfd} = (\Delta p/L)_{\text{Eq. (16)}}\,[1 + (14.5566 - 0.1342Q)W_{fm}] \tag{17}$$

where

Δp = pressure, in. of water
L = bed depth, ft
Q = airflow rate, cfm/ft^2
W_{fm} = decimal fraction of fine material, by weight. Fine material is defined as broken grain and other matter that will pass through a 12/64-in. round hole sieve.

Grama *et al.* (1984) reported the effect of fine material particle size distribution on resistance. They also report the effect of the increased resistance from fines on fan power requirements. Kumar and Muir (1986) report the effects of fines in wheat and barley.

Bulk density can have a significant effect on airflow resistance. For moderate heights of 14 to 24 ft, drop height does not affect bulk density in bins filled with a spout (Chang *et al.* 1986). Bern *et al.* (1982) reported that auger stirring can decrease the bulk density of bins filled with a grain spreader but has no effect or increases bulk density in bins filled by gravity. The magnitudes of the increases in bulk density caused by grain spreaders have been reported by Stephens and Foster (1976b, 1978) and Chang *et al.* (1983). In such cases, the pressure drop per foot is routinely corrected by multiplying the value from Equation (16) by a packing factor. A value of 1.5 is frequently used. If the bulk density is known or can be accurately estimated, the pressure drop for shelled corn can be estimated using the following equation (ASAE 1990):

$$\frac{\Delta p}{L} = X_1 + X_2 \frac{(\rho_b/\rho_k)^2\, Q}{[1-(\rho_b/\rho_k)]^3} + X_3 \frac{(\rho_\beta/\rho_k)\, Q^2}{[1-(\rho_b/\rho_k)]^3} \tag{18}$$

where

Δp = pressure drop, in. of water
L = bed depth, ft
ρ_b = corn bulk density, lb/ft^3
ρ_k = corn kernel density, lb/ft^3
Q = airflow, cfm/ft^2
X_1, X_2, X_3 = constants (Table 6)

Kumar and Muir (1986) report on the effect of filling method on the airflow resistance of wheat and barley. Jayas *et al.* (1987) showed that the resistance of canola to airflow in a horizontal direction was 0.5 to 0.7 times the resistance to airflow for the vertical direction.

Moisture content also affects airflow resistance. Its effect may, in part, be caused by its influence on bulk density. Shedd's curves include a footnote recommending that for loose fill of clean grain, airflow resistance should be multiplied by 0.80 if the grain is in equilibrium with air at relative humidities greater than 85% (ASAE 1990). At 70 °F, this corresponds to a moisture of 18% or more for shelled corn (Figure 1). Haque *et al.* (1982) give equations that correct for the effects of moisture content of shelled corn, sorghum, and wheat.

When the flow lines are parallel and airflow is linear (as is the case in a drying bin with a full perforated floor), calculation of the airflow is a straightforward application of Equation (16). For a given fan attached to a particular bin filled to a uniform depth with grain, the operating point of the fan can be determined as follows. A curve is plotted showing the total static pressure in the bin plenum versus airflow to the bin. Airflow rate is calculated by dividing the total air volume supplied to the plenum by the cross-sectional area of the bin. Using Equation (16), the pressure drop per unit depth can be calculated and multiplied by the total depth of grain in the bin to give total static pressure in the plenum. The fan curve showing air delivery volume versus static pressure can be plotted on the same axes. The intersection of the curves is the operating point for the fan. These calculations can also be done on a computer, and the point of intersection of the curves can be determined using appropriate numerical methods. McKenzie *et al.* (1980) and Hellevang (1983) summarize airflow resistances for various bin and fan combinations in tabular and graphical form.

Table 5 Constants for Airflow Resistance [Equation (16)]
(ASAE 1990)

Material	Value of a	Value of b, ft^2/cfm	Range of Q, cfm/ft^2
Barley	6.76×10^{-4}	6.71×10^{-2}	1.1 - 40
Canola (rapeseed)[1]	16.48×10^{-4}	3.69×10^{-2}	4.66- 52
Ear corn	3.29×10^{-4}	1.65	10 - 69
Lentils[2]	17.15×10^{-4}	18.7×10^{-2}	0.55-116
Oats	7.62×10^{-4}	7.06×10^{-2}	1.1 - 40
Peanuts	1.20×10^{-4}	5.64×10^{-1}	6 - 60
Popcorn, White	6.92×10^{-4}	5.99×10^{-2}	1.1 - 40
Popcorn, Yellow	5.63×10^{-4}	8.94×10^{-2}	1.1 - 40
Rice, Rough	8.12×10^{-4}	6.71×10^{-2}	1.1 - 30
Rice, Long brown	6.48×10^{-4}	3.93×10^{-2}	1.1 - 32
Rice, Long milled	6.89×10^{-4}	4.24×10^{-2}	1.1 - 32
Rice, Medium brown	1.10×10^{-3}	5.53×10^{-2}	1.1 - 32
Rice, Medium milled	9.16×10^{-4}	5.38×10^{-2}	1.1 - 32
Shelled corn	6.54×10^{-4}	1.54×10^{-1}	1.1 - 60
Shelled corn, Low airflow	3.09×10^{-4}	4.34×10^{-2}	0.05- 4
Sorghum	6.70×10^{-4}	4.09×10^{-2}	1.1 - 40
Soybeans	3.22×10^{-4}	8.13×10^{-2}	1.1 - 60
Sunflower, Confectionary	3.48×10^{-4}	9.19×10^{-2}	1.1 - 35
Sunflower, Oil	7.87×10^{-4}	1.20×10^{-1}	5 -112
Wheat	8.53×10^{-4}	4.45×10^{-2}	1.1 - 40
Wheat, Low airflow	2.66×10^{-4}	1.38×10^{-2}	0.05- 4

Notes: Units for a are in. of water · min^2/ft^2.

Table 6 Constants for Equation (18) for Airflow Resistance in Shelled Corn as Function of Bulk Density, Kernel Density, and Airflow

Airflow Range, cfm/ft^2	X_1	X_2	X_3
$5.3 < Q < 26.3$	-0.0012	5.53×10^{-4}	1.62×10^{-5}
$26.3 < Q < 52.3$	-0.013	6.94×10^{-4}	1.39×10^{-5}
$52.3 < Q \leq 117$	-0.094	10.2×10^{-4}	1.23×10^{-5}

Range of applicability: corn bulk density of 45.7 to 49.9 lb/ft^3 and airflow of 5.3 to 117 cfm/ft^2.
Source: ASAE (1990), Bern and Charity (1975).

Sokhansanj and Woodward (1991) developed a design procedure for use on personal computers to select fans for near-ambient drying of grain.

In cases where airflow is nonlinear, as in conical piles or systems with air ducts, computation is complex (Miketinac and Sokhansanj 1985). Numerical methods for predicting airflow patterns have been developed and applied to bins aerated with ducts (Brooker 1969, Segerlind 1982, Khompos *et al.* 1984), conical-shaped piles (Jindal and Thompson 1972), and bins in which porosity varies within the bed (Lai 1980). Lai's study applies to bins in which filling methods have created differences in bulk density within the bin or where fine material is unevenly distributed.

Analysis of Deep Bed Drying

Ability to predict the rate at which grain dries in a given type of drier operating in specific weather conditions with a specified airflow and air temperature can assist designers in developing driers for maximum efficiency. It can also guide operators in finding the optimum way to operate their particular driers for given weather conditions. Computer simulations have helped researchers understand the mechanisms and processes involved in drying. This section references two methods for making hand calculations of drying time and then summarizes computer simulations that have been developed.

Two relatively simple prediction equations can be solved on a hand calculator. Hukill (1947, 1972) developed a widely known and used method which predicts the moisture distribution in a bed of grain during drying. A graphical presentation of one of the equations, which further simplifies calculations, is available. Hukill's method is summarized by Brooker *et al.* (1974), who give an example calculation for shelled corn drying. Barre *et al.* (1971) made further adaptations of Hukill's method, and Foster (1986) gives a historical perspective on its development and utility. Brooker *et al.* also present a technique called the *heat balance equation*, which equates the heat available in the air for drying with the amount of heat needed to evaporate the desired amount of water from the grain. Both of the above methods take into account airflow, drying air temperature and relative humidity, exit air conditions, grain moisture, and the amount of grain to be dried.

Thompson *et al.* (1968) considered a deep bed of grain to be a series of thin layers of grain stacked one on top of another. Algebraic heat and mass balances were applied to each layer, with the resulting exit air conditions of one layer becoming the input conditions of the next layer. Thompson *et al.* (1969) used the model to predict concurrent flow, crossflow, and counterflow drying of shelled corn. Paulsen and Thompson (1973) used it to evaluate crossflow drying of sorghum. Stevens and Thompson (1976) and Pierce and Thompson (1981) used the model to make recommendations about optimum design of high-temperature grain driers.

Bakker-Arkema *et al.* (1978) used simultaneous heat and mass transfer equations in a series of coupled partial differential equations to describe deep bed drying. The equations, solved using a finite difference technique, predict grain temperature, grain moisture content, and air temperature and humidity ratio. Bakker-Arkema *et al.* (1979, 1984) give solutions for in-bin, batch, continuous crossflow, and continuous concurrent flow driers. Morey *et al.* (1976) used the model to evaluate energy requirements for drying. Morey and Li (1984) and Bakker-Arkema *et al.* (1983) demonstrated the effect of thin layer drying rate on the model predictions.

Other researchers have also developed simulation models. Hamdy and Barre (1970) developed a hybrid computer simulation of high-temperature drying and compared predictions to data on moisture and temperature measurements in a laboratory crossflow drier. Bridges *et al.* (1980) used the Thompson model for simulation of batch-in-bin drying. Morey *et al.* (1978) and Parry (1985) review many of the mathematical models used for high-temperature grain drying.

Computer simulations have also been developed for low-temperature and solar drying. Some of these models have been referenced in the section Fungal Growth and Mycotoxins under Prevention of Deterioration. Thompson (1972) developed a model that was later used by Pierce and Thompson (1979) to make recommendations on airflow in solar grain drying and by Pierce (1986) to evaluate natural air drying. Sabbah *et al.* (1979) used the logarithmic model of Barre *et al.* (1971) for simulation of solar grain drying. Bridges *et al.* (1984) used a model to evaluate the economics of stirring devices in in-bin drying systems. Morey *et al.* (1979), Fraser and Muir (1981), Bowden *et al.* (1983), and Smith and Bailey (1983) have also modeled low-temperature drying. Sharp (1982) reviewed low-temperature drying simulation models.

Aeration of Grain

Aeration involves forcing small amounts of air through the stored grain to maintain a uniform temperature. Prior to the development of this concept, grain was turned by moving it from one storage bin to another. Foster (1986) credits Hukill *et al.* (1953) with developing the concept. As mentioned in the previous sections Fungal Growth and Mycotoxins and Insect Infestation, lowering of the grain temperature during winter in temperate climates can reduce the rate of deterioration from molds and insects. Aeration can also prevent temperature gradients from developing within the grain mass. Such gradients can cause moisture migration, which results in unacceptably high moistures in certain portions of the bin.

Aeration is used to cool stored grain in the fall. A typical practice is to aerate the grain when the difference between grain temperature and average daily outside temperature exceeds 10°F. In the United States, grain is usually not warmed in the spring unless it is to be stored past July. Foster and McKenzie (1979) and McKenzie (1980) give practical recommendations for aeration of grain. Airflow rates of 0.025 to 0.5 cfm per bushel are normally used. Air is usually distributed through the bottom of the bin using ducts. Duct spacing and fan selection are related to bin size and shape and the airflow rate. Foster and Tuite (1982) give an overview of the topic and include information and charts used for design of such systems. Peterson (1982) gives recommendations for duct spacing in flat storages.

Several computer simulations have been developed to study the effects of heat buildup from microbial activity with and without aeration (Thompson 1972, Brooker and Duggal 1982, Metzger and Muir 1983, Lissik 1986). Aldis and Foster (1977) and Schultz *et al.* (1984) studied the effect of aeration on grain moisture changes.

DRYING SPECIFIC CROPS

Hay

Forage crops can be harvested, dried, and stored as hay, or harvested and stored under anaerobic conditions as grass silage. Hay quality can be judged by its color, leafiness, and appearance. Laboratory tests and feeding trials give a more detailed picture of hay quality. The traditional method of making hay is to mow the forage and allow it to field cure or dry in the swath and windrow. More recently, harvesting at higher moistures with subsequent artificial drying has become feasible.

Basic principles of hay drying and storage are covered by Hall (1980) and Schuler *et al.* (1986). Forage must be harvested in the proper stage of maturity to attain maximum feeding value. Leaf loss from alfalfa is high when it is handled at moistures below 39%. Therefore, if it is baled at 40% moisture and dried artificially to the recommended storage moisture of 20% (Schuler *et al.*

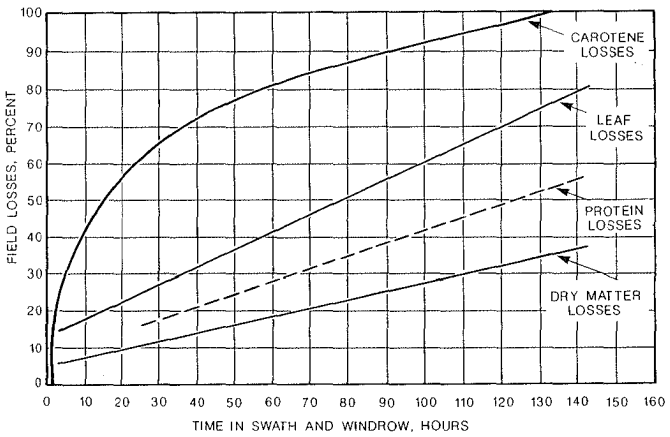

Fig. 3 Relation between Time in Swath and Windrow and Field Losses of Leaves, Dry Matter, Protein, and Carotene

(1986), a significantly higher feeding value can be achieved. Both Schuler *et al.* (1986) and Hall (1980) give sketches for batch and in-storage hay driers. They recommend airflows of 15 to 20 cfm per square foot of mow floor area or 200 to 500 cfm per ton.

Dehydrated alfalfa meal supplies provitamin A (carotene), vitamin E, xanthophylls (poultry pigmenting factors), vitamin K, vitamin C, and B vitamins. Figure 3 shows losses from field drying of hay found in tests conducted by Shepherd (1954). The rapid loss of carotene immediately after the forage is cut indicates the need for rapid transport to the dehydrator when alfalfa meal with high vitamin content is desired.

Several factors influence retention of vitamins during storage, such as the starting plant material, dehydration conditions, addition of stabilizers, and storage conditions. Lowering the temperature reduces the loss rate. Inert gas atmosphere in storage also reduces losses (Hoffman *et al.* 1945). According to Shepherd (1954), blanching of fresh alfalfa before drying does not alter the storage stability of carotene. Table 7 shows Shepherd's results on the effect of prolonged heating at 212°F. The alfalfa was dried after 45 min; heating beyond this time represented excessive exposure to this temperature. Carotene retention in the intact meal at 150°F storage temperature was considered a measure of storage stability. Normal storage moisture is 8 to 9%. Thompson *et al.* (1960) summarize the effects of over- and underdrying on carotene stability.

Drying and handling of large round bales has been researched. These bales may weigh from 850 to 1500 lbs and are handled individually with forklifts. Verma and Nelson (1983) studied storage of large round bales and found that dry matter loss was the primary component of the total storage losses. Bales stored so that they were protected from the weather had lower losses of dry matter than bales exposed to the weather. They were also higher in total protein.

Table 7 Effect of Heating Chopped Alfalfa on Carotene Loss during Subsequent Storage of Meal
(Thompson *et al.* 1960)

Hours in Oven at 212°F	Initial Carotene, ppm	Carotene Retained 7 Days at 149°F, %
0.75	229	37
1	228	37
2	197	37
3	176	28
4	149	21
5.5	112	18
7.5	86	15

Note: Alfalfa is fresh frozen from Ryer Island, CA.

Jones *et al.* (1985) found significant dry matter losses in large round bales of mature fescue hay. Harrison (1985) found that addition of sulfur dioxide at the rate of 1% of dry matter had little effect on dry matter loss and nutrient contents for a mixture of alfalfa and brome grass. However, bales protected with plastic bags did have significantly lower dry matter losses. Jones *et al.* (1985) found that bales of mature fescue hay stored inside and bales treated with ammonia had less dry matter loss and higher in-vitro dry matter digestibility. Henry *et al.* (1977) and Frisby *et al.* (1985) developed and tested solar driers for large round bales.

Grain

The physiological factors involved in drying and storing grain are different from those of forages. Grain is the end product of plant growth, and most physiological activity within the grain or seed is approaching a low level when harvested. With forage, the biological activity within the plant is at or near its peak at the time of harvest.

Deterioration of grain harvested at moistures above those safe for storage and the chemical preservation of grain is addressed in the section Fungal Growth and Mycotoxins. Preservation by ensiling or airtight storage is addressed in the section Oxygen and Carbon Dioxide.

Corn

Shelled field corn is used primarily as livestock feed, but some is used by milling or processing industries for manufacturing starch, corn oil, and other products. Little information is available on the relationship between the drying method and the feed value of corn. Market grade, as established by the USDA Agricultural Marketing Service, is the primary criterion for determining corn value. Tests by Cabell *et al.* (1958) indicated that shelled corn with a moisture content of 29 to 32% can be dried without loss of protein nutritive value by air with temperatures as high as 240°F, provided the airflow rate is approximately 110 cfm/bu.

The market grade of dry corn is affected more by the amount of fine material than by other grading factors. Fine material is defined as the broken grain and other material that passes through a 12/64-in. round-holed sieve. The brittleness imparted to the corn during drying or the physical damage done to wet corn causes it to break each time it is handled. The propensity of corn to break during subsequent handling, called *breakage susceptibility*, can be measured with a multiple-impact device called the *Stein breakage tester*. Stephens and Foster (1976a) demonstrated that corn breakage in the tester was correlated with damage during handling. Watson *et al.* (1986) give a standardized procedure for using the Stein breakage tester, and Watson and Herum (1986) describe and compare other devices developed for measurement of breakage susceptibility. They concluded that a device developed by Singh and Finner (1983) offers great potential for testing of grain for breakage susceptibility in commercial situations.

Paulsen *et al.* (1983) found significant variations in breakage susceptibility among hybrids. Corn dried with air at high temperatures (140°F) was two to six times more susceptible to breakage than corn dried at near-ambient temperatures. Gustafson and Morey (1979) found that delayed cooling (maintaining the corn at or near its temperature at the end of drying for 6 to 12 h) reduced breakage susceptibility and improved the test weight.

In a study of combination drying, Gustafson *et al.* (1978) found that combination drying (high-temperature drying to 18% followed by low-temperature drying to 16.6% moisture or below) significantly decreased the increase in breakage susceptibility normally caused by high-temperature drying. Morey and Cloud (1980) summarize principles, energy savings, and advantages of combination drying.

Both drying temperature and corn hybrid can affect the quality of shelled corn for specific end uses. Brekke *et al.* (1973) found

that drying at temperatures above 140°F decreased the quality of the corn for dry milling. Peplinski *et al.* (1982) found that optimum dry milling quality could be achieved by harvesting corn at moistures below 25%, minimizing machinery-induced damage to the kernels, and drying at air temperatures below 180°F. Paulsen and Hill (1985) found that the yield of flaking grits from dry milling of corn was significantly greater for corn that had a high test weight and relatively low breakage susceptibility. Weller *et al.* (1987) found that variety affected wet milling quality. At drying temperatures between 120 and 160°F, protein conformational changes occurred and decreased the ethanol soluble protein. Hybrids differ in resistance to storage mold (Tuite and Foster 1979), thin layer drying rate, and dry milling quality (Stroshine *et al.* 1986). Watson (1987) gives an extensive summary of measurement and maintenance of quality of corn, and Foster (1975) summarizes approaches to reducing damage during harvesting, handling, and drying.

Cotton

The lint moisture content for best results in ginning cotton appears to be 5 to 7%, with an optimum moisture content of 6% (Franks and Shaw 1962). Cotton, like grain, is hygroscopic and should be dried just prior to ginning. The wide variation in incoming moisture content usually requires different amounts of drying for each load. Rapid changes in the amount of drying required can best be handled by using a multipath drying tower in which the cotton is exposed for various lengths of time (2 to 10 s) at temperatures not exceeding 350°F. The air-to-cotton ratio can range from 40 to 100 cfm/lb of cotton (Franks and Shaw 1962). Laird and Baker (1983) found that substantial amounts of heat could be reclaimed and used for drying in commercial cotton gin plants. Equilibrium moisture content data for newly harvested cotton fibers is given by Griffin (1974). Anthony (1982) studied moisture gain of cotton bales during storage.

Cottonseed removed from the fibers is also dried. The germination of cottonseed is unimpaired by drying if the internal cottonseed temperatures do not exceed 140°F (Franks and Shaw 1962). This temperature is not exceeded in the tower drier described previously. However, the moisture content of the seed can be above the recommended level of 12% following the multipath tower drying. Drying seed in a triple-pass drum at 250 to 300°F with an exposure time of 4 min, followed by cooling, reduces moisture content, inhibiting formation of free fatty acids, and improving germination over undried seed. Anthony (1983) dried cottonseed in a microwave drier. The cottonseed would not germinate, but its oil properties were not harmed as long as lower temperatures were used. The drying rate was increased by reducing pressure below atmospheric. Rayburn *et al.* (1978) studied preservation of high-moisture cottonseed with propionic acid.

Peanuts

Peanuts in the shell normally have a moisture content of about 50% at the time of digging. Allowing peanuts to dry on the vines in the windrows for a few days removes much of this water. However, peanuts normally contain 20 to 30% moisture when removed from the vines, and some artificial drying of peanuts in the shell is necessary. Drying should begin within 6 h after harvesting to keep peanuts from self-heating. The maximum temperature and rate of drying must be controlled to maintain quality. High temperatures result in off-flavor or bitterness. Overly rapid drying without high temperatures results in blandness or inability to develop flavor when roasted (Bailey *et al.* 1954). High temperatures and rapid or excessive drying also cause the skin to slip easily and the kernels to become brittle. These conditions result in damage in the shelling operation and can be avoided if the moisture removal rate does not exceed 0.5% per hour. Because of these limitations, continuous-flow drying is not usually recommended.

Young (1984) found energy savings up to 26% when comparing recirculating driers with conventional peanut driers. Smith and Davidson (1982) and Smith *et al.* (1985) address the aeration of peanuts during warehouse storage.

Rice

Of all grains, rice is possibly the most difficult to process without quality loss. Rice containing more than 12.5% moisture cannot be stored safely for long periods, yet the recommended harvest moisture content for best milling and germination ranges from 20 to 26% (Kramer 1951). If harvested at this moisture content, drying must begin promptly to prevent heat-related damage which can result in "stack-burn," a yellowing of the kernel. To prevent excessive internal fissuring, which results in broken kernels during milling, multiple-pass drying is usually necessary (Calderwood and Webb 1971). Kunze and Calderwood (1980) summarize rice drying techniques.

Since the market demands polished whole kernels of rice, it is necessary to prevent damage in the form of fissures. Rapid moisture removal or addition can create moisture gradients within kernels. According to Kunze (1984), gradients can develop in the field on a humid night before harvest, in a hopper containing a mixture of rice kernels at varying moistures, and in certain types of driers. Banaszek and Siebenmorgen (1990) quantified the rate at which moisture adsorption reduces head rice yields. Velupillai and Verma (1986) report that drying at 200°F followed by tempering in a sealed container for 24 h gave good kernel strength and head rice yields. They also found that storing the rice after drying for 3 weeks gave optimum grain quality. Bakker-Arkema *et al.* (1984) achieved good rice quality with concurrent flow drying of rice.

Soybean, Sunflower, and Edible Beans

Prolonged periods of extremely wet weather during the harvest season can make artificial drying of soybeans necessary. Like peanuts and other oilseeds, soybeans cannot be dried satisfactorily with the high-temperature, high-speed methods used for cereal grains. Because of the different seed structure, rapid drying splits the seed coat and reduces quality and storage life. Overhults *et al.* (1975) report a significant decrease in the quality of oil extracted from soybeans dried at temperatures above 160°F. Soybeans have one of the slowest thin layer drying rates of commonly grown cereals and oilseeds (Bakker-Arkema *et al.* 1983). Therefore, they dry slower and require more energy when dried in continuous-flow driers.

Sunflower is a major crop in some areas of the United States. Hellevang (1987) recommends maximum drying temperatures of up to 200°F for continuous-flow drying of oil sunflower and maximum drying temperatures of 180°F for non-oil sunflowers, where scorching of the seed meat should be prevented. Schuler (1974) gives data on equilibrium moisture, airflow resistance, and specific heat of sunflower seeds. Because sunflower is about half the density of shelled corn, moisture can be removed more rapidly, and there is a tendency to overdry. This factor, along with accumulation of foreign material when drying, causes an increased fire hazard (Hellevang 1982). Schmidt and Backer (1980) attribute most of the problems encountered with storage of sunflower seed to improper drying or aeration.

Edible beans, a major crop in several states, should be dried with air at relative humidities above 40% to prevent stress cracking. Natural air or low-temperature drying is best (Hellevang 1987). If dried at high rates, seed coats may crack, and beans may split during subsequent handling. Broken beans can develop a bitter or undesirable flavor and spoil more easily during storage.

Wheat and Barley

In northern regions of the United States, wheat and barley may be harvested above safe storage moistures to prevent excessive

field losses. Moilanen *et al.* (1973) recommended that hard red spring wheat be dried at temperatures below 160, 140, and 120°F, respectively, for harvest moistures of 16, 20, and 24% wet basis. These data assumed airflows of 100 to 150 cfm/ft^2. For airflows of 50 cfm/ft^2, they recommended that the drying air temperature be reduced by 10 to 15°F. In the case of barley used for malting, the seed must be able to germinate. Therefore, the maximum recommended drying air temperature is 110 to 120°F (Hellevang 1987). Watson *et al.* (1962) studied the effects of harvest moisture and drying temperature on barley malting quality and recommended harvesting below 20% moisture. If wheat or barley is used for seed, the maximum recommended drying air temperature is 110°F.

In regions where soft wheat is grown, it may be economical to harvest at 20 to 24% moisture to allow double cropping with soybeans; this allows wheat harvest to begin 5 to 7 days earlier than normal and increases the yield of the soybeans (Swearingen 1979). In areas where double cropping is feasible, soft wheat can be dried using low-temperature solar drying or ambient drying with intermittent fan operation (Barrett *et al.* 1981). High-speed and continuous-flow systems with reduced drying air temperatures can also be used (Parsons *et al.* 1979). Kirleis *et al.* (1982) harvested soft red winter wheat at moistures of 25% or below and dried with air temperatures of 150°F or below without adverse effects on milling or cookie baking quality.

In high-temperature continuous-flow driers, wheat or barley reduce airflow because they have a high airflow resistance. Bakker-Arkema *et al.* (1983) report that thin layer drying rates of barley and wheat are much faster than for corn. Barley dries more slowly than wheat, presumably because the kernels are larger. In their computer simulations of a concurrent-flow drier, wet bushel capacity for wheat was about 80% of the capacity for shelled corn when 4.7 percentage points of moisture were removed. The drying capacity difference was probably caused by a decrease in airflow.

Tobacco (Curing)

Tobacco leaves normally have a moisture content of about 85% at harvest. The major methods of tobacco drying are *air curing* and *flue curing* (Johnson *et al.* 1960). For air curing, whole plants are cut and allowed to wilt in the field until the leaves reach about 70% moisture. Plants are then hung in open barns, where temperatures range from 60 to 90°F and humidities from 65 to 70%. The curing period is 28 to 56 days (Jefries 1940). The desired end product is a tan leaf. Overdrying at low temperatures results in green color and low sugar content; overdrying at high temperatures results in yellow color (Walton and Henson 1971). Both conditions are undesirable, since the normal chemical changes are arrested prematurely. Subsequent drying at optimum rates can reverse some damage. Underdrying at all temperatures results in undesirable dark color and damage from mold and bacterial growth (Walton *et al.* 1973).

Flue curing uses artificial heat. The leaves are harvested and hung in closed barns where temperatures are increased gradually during the curing period. Normally, 3 days of drying at temperatures of 90 to 120°F bring about yellowing. For the next 2 days, temperatures of 120 to 140°F are used for leaf drying; then, stems are dried using temperatures of 170°F for 1 to 2 days. A bright yellow to orange color is desirable in flue-cured or bright-leaf tobacco.

CHAPTER 11

AIR CONTAMINANTS

Air Contaminants 11.1
Nature of Airborne Contaminants 11.2
Suspended Particulates 11.2
Industrial Air Contaminants 11.4
Flammable Gases and Vapors 11.4
Combustible Dusts 11.5
Air Pollution 11.5
Radioactive Air Contaminants 11.6
Atmospheric Pollen 11.6
Airborne Microorganisms 11.7
Indoor Air Quality 11.8

AIR is composed of many gases. The gaseous components of clean, dry air near sea level are approximately 21% oxygen, 78% nitrogen, 1% argon, and 0.03% carbon dioxide. Also included are trace amounts of hydrogen, neon, krypton, helium, ozone, and xenon, in addition to varying amounts of water vapor and small quantities of microscopic and submicroscopic solid matter called *permanent atmospheric impurities.*

Air composition may be changed accidentally or deliberately. In sewers, sewage treatment plants, tunnels, and mines, the oxygen content of air can become so low that people cannot remain conscious or survive. Concentrations of people in confined spaces (theaters, survival shelters, submarines) require that carbon dioxide given off by normal respiratory functions be removed and replaced with oxygen. Pilots of high-altitude aircraft, breathing at greatly reduced pressure, require systems that increase oxygen concentration. Conversely, for divers working at extreme depths, it is common to increase the percentage of helium in the atmosphere and reduce nitrogen and sometimes oxygen concentrations.

At atmospheric pressure, oxygen concentrations of less than 12% or carbon dioxide concentrations greater than 5% are dangerous, even for short periods.

Lesser deviations from normal composition can be hazardous under prolonged exposures. Chapter 11 of the 1991 ASHRAE *Handbook—Applications* details acceptable variations in composition. Chapter 37 further details environmental health issues.

AIR CONTAMINANTS

Normal air contains varying amounts of foreign materials (*permanent atmospheric impurities*). These materials can arise from natural processes such as wind erosion, sea spray evaporation, and volcanic eruption. The concentrations in the air vary but are usually less than the concentrations caused by human activity.

Man-made contaminants are many and varied, originating from numerous areas of human activity. Electric power-generating plants, various modes of transportation, industrial processes, mining and smelting, construction, and agriculture generate large amounts of contaminants. Contaminants that present particular problems in the indoor environment include, among others, tobacco smoke, radon, and formaldehyde.

Air contaminants can be classified as follows:

- Particulate or gaseous
- Organic or inorganic
- Visible or invisible
- Submicroscopic, microscopic, or macroscopic
- Toxic or harmless
- Stable or unstable

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment, in conjunction with TC 2.4, Particulate Air Contaminants and Particulate Contaminant Removal Equipment.

Loose classifications based on the phase of the suspended contaminant (solid, liquid, or gas) and method of formation of the contaminant are as follows:

- Dusts, fumes, and smokes that are solid particulate matter, although smoke often contains liquid particulates.
- Mists, fogs, and smokes that are suspended liquid particulates.
- Vapors and gases.

Dusts, Fumes, and Smokes

Dusts are solid particles projected into the air by natural forces such as wind, volcanic eruption, or earthquakes, or by mechanical processes including crushing, grinding, demolition, blasting, drilling, shoveling, screening, and sweeping. Some of these forces produce dusts by reducing larger masses, while others disperse materials that have already been reduced.

Particles are not dust unless they are smaller than about 100 μm. Dusts can be mineral, such as rock, metal, or clay; vegetable, such as grain, flour, wood, cotton, or pollen; or animal, including wool, hair, silk, feathers, and leather.

Fumes are solid particles formed by condensation of vapors of solid materials. Metallic fumes are generated from molten metals and usually occur as oxides because of the highly reactive nature of finely divided matter. Fumes can also be formed by sublimation, distillation, or chemical reaction. Such processes create airborne particles smaller than 1 μm. Fumes permitted to age may agglomerate into larger clusters.

Smokes are small solid and/or liquid particles produced by incomplete combustion of organic substances such as tobacco, wood, coal, oil, and other carbonaceous materials. The term smoke is applied to a mixture of solid, liquid, and gaseous products, although technical literature distinguishes between such components as soot or carbon particles, flyash, cinders, tarry matter, unburned gases, and gaseous combustion products. Smoke particles vary in size—the smallest being much less than 1 μm. The average is often in the range of 0.1 to 0.3 μm.

Environmental tobacco smoke consists of a suspension of small 0.01 to 1.0 μm (mass median diameter of 0.5 μm) liquid particles that form as the superheated vapors leaving the burning tobacco condense. Also produced are numerous gaseous contaminants including carbon monoxide.

Viruses range in size from 0.003 to 0.06 μm, although they usually occur in colonies or attached to other particles. Most *bacteria* range between 0.4 and 5 μm and are usually associated with large particles. *Fungus* spores are usually from 10 to 30 μm, while *pollen* grains are from 10 to 100 μm, with many common varieties in the 20 to 40 μm range. Airborne viruses, bacteria, pollen, and fungus spores are sometimes referred to as *bioaerosols.*

Mists and Fogs

Mists are small airborne droplets of materials that are ordinarily liquid at normal temperatures and pressure. They can be formed

by atomizing, spraying, mixing, violent chemical reactions, evolution of gas from liquid, or escape as a dissolved gas when pressure is released. Small droplets expelled or atomized by sneezing constitute mists containing microorganisms that become air contaminants.

Fogs are fine airborne droplets usually formed by condensation of vapor. Fog nozzles are named for their ability to produce extra fine droplets, as compared with mists from ordinary spray devices. Many droplets in fogs or clouds are microscopic and submicroscopic and serve as a transition stage between larger mists and vapors.

The volatile nature of most liquids reduces the size of their airborne droplets from the mist to the fog range and eventually to the vapor phase, until the air becomes saturated with that liquid. If solid material is suspended or dissolved in the liquid droplet, it remains in the air as particulate contamination. For example, sea spray evaporates fairly rapidly, generating a large number of fine salt particles that remain suspended in the atmosphere.

Smog commonly refers to air pollution; it implies an air mixture of smoke particles, mists, and fog droplets of such concentration and composition as to impair visibility, in addition to being irritating or harmful. The composition varies among different locations and at different times. The term is often applied to haze caused by a sunlight-induced photochemical reaction involving the materials in automobile exhausts. Smog is often associated with temperature inversions in the atmosphere that prevent normal dispersion of contaminants.

Vapors and Gases

The terms gas and vapor are often used to describe a common state of a substance. Gas is normally used to describe any mixture, except atmospheric air, that exists in the gaseous state at normal atmospheric conditions. Examples are oxygen, helium, and nitrogen. Vapor is used to describe a substance in the gaseous state that can also exist as a liquid or solid at normal atmospheric conditions. Examples include gasoline, benzine, carbon tetrachloride, and water.

NATURE OF AIRBORNE CONTAMINANTS

Sizes of Airborne Particles

Figure 1 shows the sizes and characteristics of airborne solids and liquids. Particles less than 0.1 μm begin to behave similarly to gas molecules, traveling with Brownian movement and with no predictable or measurable settling velocity. Particles in the range from 0.1 to 1 μm have settling velocities that can be calculated but are so low that settling is usually negligible, since normal air currents counteract any settling. On a particle count basis, over 99% of the particles in a typical atmosphere are below 1 μm.

Particles in the 1 to 10 μm range settle in still air at constant and appreciable velocity. However, normal air currents keep them in suspension for appreciable periods.

Industrial hygienists are primarily concerned with particles less than 2 μm, since this is the range of sizes most likely to be retained in the lungs (Morrow 1964). Particles larger than 8 to 10 μm in diameter are separated and retained by the upper respiratory tract. Intermediate sizes are deposited mainly in the conducting airways of the lungs, from which they are rapidly cleared and swallowed or coughed out. About 50% or less of the particles in inhaled air settle in the respiratory tract.

Particles larger than 10 μm settle fairly rapidly and can be found suspended in air only near their source or under strong wind conditions. Exceptions are lint and other light fibrous materials, such as portions of certain weed seeds, which remain suspended longer. Most individual particles 10 μm or larger are visible to the naked eye under favorable conditions of lighting and contrast. Smaller particles are visible in high concentrations. Cigarette smoke (with an average particle size less than 0.5 μm) and clouds are common examples.

Table 1 Relation of Screen Mesh to Particle Size

U.S. Standard sieve mesh	400	325	200	140	100	60	35	18
Nominal sieve opening in μm	37	44	74	105	149	250	500	1000

Direct fallout in the vicinity of the dispersing stack or flue and other nuisance problems of air pollution involve larger particles. Smaller particles, as well as mists, fogs, and fumes generated, remain in suspension longer. In this size range, meteorology and topography are more important than physical characteristics of the particles. Since settling velocities are small, the ability of the atmosphere to disperse these small particles depends largely on local weather conditions.

Comparison is often made to screen sizes used for grading useful industrial dusts and granular materials. Table 1 illustrates the relation of U.S. Standard sieve mesh to particle size in micrometres. Particles above 40 μm are the screen sizes, and those below are the subscreen or microscopic sizes.

Particle Size Distribution

The particle size distribution in any sample can be expressed as the percentage of the number of particles smaller than a specified size. The upper curve of Figure 2 shows these data plotted for typical atmospheric contamination (Whitby *et al.* 1955, 1957). The middle curve shows the percentage of the total projected area of the particles contributed by particles less than a specified size. The lower curve shows the percentage of the total particle weight contributed by those particles less than a given size.

The differences among values presented by the three curves should be noted. For example, particles 0.1 μm or less in diameter (but still above electron microscope minimum detection size of about 0.005 μm) make up 80% of the number of particles in the atmosphere but contribute only 1% of the mass. Also, the 0.1% of particles by number larger than 1 μm carry 70% of the total mass, which is the direct result of the mass of a spherical particle increasing as the cube of its diameter. Although most of the mass is contributed by intermediate and larger particles, about 80% of the contamination is supplied by particles less than 5 μm in diameter. Most of the staining effect results from particles less than 1 μm in diameter. Suspended particles in urban air are predominantly smaller than 1 μm (expressed as equivalent spheres of unit density) and have a distribution that is approximately log-normal.

SUSPENDED PARTICULATES

The total amount of suspended particulate matter in the atmosphere can influence the loading rate of air filters and their selection. The amount of soot that falls in U.S. cities ranges from 20 to 200 ton/mile^2 per month. Soot fall data indicate effectiveness of smoke abatement and proper combustion methods and serve as comparative indices of such control programs. These values have little significance to the ventilating and air-conditioning engineer, since they do not express any measure of the suspended material that must be cleaned from the ventilation air before it can be used.

In particle count, the number of suspended particulates is enormous. A room with heavy cigarette smoke has a total particle concentration of $30 \times 10^6/ft^3$; even clean air contains over 10^6 particles/ft^3. If smaller particles detectable by other means, such an electron microscope or condensation nuclei counter, are also included, the total particle count would be greater than the above concentrations by a factor of 10 to 100.

Fig. 2 Particle Size Distribution of Atmospheric Dust
[Reproduced from Whitby *et al.* (1955) by permission.]

Extensive measurements have been made of outdoor pollution, but limited data have been gathered on indoor pollution not associated with specific industrial processes. Indoor levels are influenced by the number of people and their activities, building materials and construction, outside conditions, ventilation rate, and the air-conditioning and filtration system. For further information, see the section Indoor Air Quality, Spengler *et al.* (1982), and NRC (1981).

Measurement of Airborne Particles

The quantity of dust can be determined by particle count or total mass. Another indirect method measures optical density of the collected dust based on the projected area of the particles. Dust particles can be sized with graduated scales or optical comparisons, using a standard microscope. The lower limit for sizing with the light field microscope is approximately 0.9 μm, depending on the vision of the observer, the dust color, and the contrast available. This size can be reduced to about 0.4 μm by using oil immersion objective techniques. Dark field microscopic techniques reveal particles smaller than these, to a limit of approximately 0.1 μm. Smaller submicroscopic dusts can be sized and compared with the aid of an electron microscope. Other sizing techniques may take into account velocity of samplings in calibrated devices and actual settlement measurements in laboratory equipment. The electron microscope and various sampling instruments, such as the cascade impacter, have been successful in sizing particulates, including fogs and mists.

Instruments have been developed and test methods devised for continuous counting and sizing of airborne contaminants. These instruments use the light-scattering principle and, depending on the model, can detect particles down to 0.3 μm. Instruments using laser light sources can detect particles down to 0.1μm (ASTM 1983). A condensation nucleus counter can count submicrometric particles to below 0.01 μm. These particles, present in great numbers in the atmosphere, serve as nuclei for condensation of water vapor (Scala 1963).

Each of the various methods of measuring particle size distribution gives a different value for the same size particle, since different properties are actually measured. For example, a microscopic technique may measure longest dimension, while impacter results are based on aerodynamic behavior (ACGIH 1983).

INDUSTRIAL AIR CONTAMINANTS

Many industrial processes produce air contaminants in the form of dusts, fumes, smokes, mists, vapors, and gases. Contaminants should be controlled at the source so that they are not dispersed through the factory nor allowed to increase to toxic concentration levels. Control methods are covered in Chapter 10 of the 1992 ASHRAE *Handbook—Systems and Equipment* and Chapters 25 and 27 of the 1991 *Applications* volume.

Zero concentration of all contaminants is not economically feasible. Absolute control of all contaminants cannot be maintained, and workers can assimilate small quantities of various toxic materials without injury. Industrial hygiene science is based on the fact that most air contaminants become toxic only if their concentration exceeds a maximum allowable limit for a specified period.

Mandatory U.S. standards promulgated by the Occupational Safety and Health Administration (OSHA) are published initially in the Federal Register and then in the Code of Federal Regulations (29 CFR 1910.1000), which is revised annually. Most of the standards promulgated initially by OSHA were those previously recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) and the American Industrial Hygiene Association. The health effects on which these standards were based can be found in their publications (ACGIH 1987). Revisions of the initial OSHA standards are now recommended by the National Institute of Occupational Safety and Health (NIOSH) and are published in a series of individual criteria documents. For protection of nonindustrial occupants such as office workers, which may include sensitive persons, indoor concentrations should be kept below the ACGIH threshold limit values (see ASHRAE *Standard* 62-1989).

FLAMMABLE GASES AND VAPORS

The use of flammable materials is widespread. Flammable gases and vapors (NFPA 1984) can be found in sewage treatment plants, sewage and utility tunnels, dry-cleaning plants, automobile garages, and industrial finishing process plants. Adequate ventilation minimizes or prevents fires and explosions and is necessary, regardless of other precautions, such as elimination of the ignition sources, safe building construction, and the use of automatic alarm and extinguisher systems.

A flammable liquid's vapor pressure and volatility or rate of evaporation determines its ability to form an explosive mixture. These properties can be expressed by the flash point, which is the temperature to which a combustible liquid must be heated to produce a flash when a small flame is passed across the surface of the liquid. Depending on the test methods, either the open cup or closed cup flash point may be listed. The higher the flash point, the more safely the liquid can be handled. Liquids with flash points under 70°F should be regarded as highly flammable.

In practice, the air-vapor or air-gas mixture must be in the *explosive range* before it can be ignited. The explosive range is the range between the upper and lower explosive limits, expressed as percent by volume in air. Concentrations of material above the higher range or below the lower range will not explode. The range for many chemicals is found in National Fire Code bulletins published by the National Fire Protection Association (NFPA). Some representative limits of flammability are listed in Table 2.

Chapter 27 of the 1991 ASHRAE *Handbook—Applications* covers equipment for control of combustible materials. In designing ventilation systems to control flammable gases and vapors, the engineer must consider the following:

Table 2 Flammable Limits of Some Gases and Vapors

Gas or Vapor	Flash Point, °F	Flammable Limits, % by Volume	
		Lower	Upper
Acetone	0	2.6	12.8
Ammonia	Gas	16	25
Benzene (benzol)	12	1.3	7.1
n-Butane	Gas	1.9	8.5
Carbon disulfide	−22	1.3	44
Carbon monoxide	Gas	12.5	74
1,2-Dichloroethylene	43	9.7	12
Diethyl ether	−49	1.9	48
Ethyl alcohol	55	4.3	19
Ethylene	Gas	3.1	32
Gasoline	−45	1.4	7.6
Hydrogen	Gas	4.0	75
Hydrogen sulfide	Gas	4.3	45
Isopropyl alcohol	53	2.0	12
Methyl alcohol	52	7.3	36
Methyl ethyl ketone	21	1.8	10
Natural gas (variable)	Gas	3.8	17
Naphtha (benzine)	50	0.9	6.7
Propane	Gas	2.2	9.5
Toluene (toluol)	40	1.2	7.1
o-xylene	90	1.0	6.0

1. Most safety authorities and fire underwriters prefer to limit concentrations to 20 to 25% of the lower explosive limit of a material. The resulting safety factor of 4 or 5 allows latitude for imperfections in air distribution and variations of temperature or mixture, and guards against unpredictable or unrecognized sources of ignition. Operation at concentrations above the upper explosive limit should be resorted to only in rare instances. To reach the upper explosive limit, the flammable gas or vapor must pass through the active explosive range, in which any source of ignition causes an explosion. In addition, a drop in gas concentration due to unforeseen dilution or reduced evaporation rate results in operation in the dangerous explosive range.
2. In occupied places where ventilation is applied for proper health control, the danger of an explosion is minimized. In most instances, flammable gases and vapors are also toxic, and the maximum allowable concentrations are far below the lower explosive limit of the material. For example, proper ventilation for acetone vapors keeps the concentration below 1000 ppm. This is equivalent to 0.1% by mass. The lower explosive limit for acetone is 2.5% by volume.
3. Proper location of exhaust and supply ventilation equipment depends primarily on how the contaminant is given off and on other problems of the process, and secondarily on the relative density of flammable vapor.

The specific density of the explosive mixture is the same as that of air. Cross drafts, moving equipment, and temperature differentials may cause sufficient mixing to produce explosive concentrations and disperse these throughout the atmosphere, without regard to heavier-than-air vapors. Therefore, the engineer must either provide proper exhaust and supply air patterns to control the hazardous material, preferably at its source, or offset the effects of drafts, equipment movement, and convective forces by providing good distribution of exhaust and supply air for general dilution and exhaust. The intake duct should be positioned so that it does not bring in exhaust gases or emissions from ambient sources.

COMBUSTIBLE DUSTS

Many organic and some mineral dusts can produce dust explosions (Hartmann 1958). Often, a primary explosion results from a small amount of dust in suspension that has been exposed to a source of ignition; the pressure and vibration created can dislodge large accumulations of dust on horizontal surfaces, creating a larger secondary explosion.

For ignition, dust clouds require high temperatures and sufficient dust concentration. These temperatures and concentrations and the minimum spark energy can be found in Avallone and Baumeister (1987).

Explosive dusts are potential hazards whenever uncontrolled dust escapes, dispersing in the atmosphere or settling on horizontal surfaces such as beams and ledges. Proper exhaust ventilation design involves the principles covered in Chapter 27 of the 1991 ASHRAE *Handbook—Applications*. The ventilation systems and equipment chosen must prevent the pocketing of dust inside the equipment. When local exhaust ventilation is used, separation equipment should be installed as close to the dust source as possible to prevent transport of dust in the exhaust system.

AIR POLLUTION

Concentration levels of outdoor pollutants vary. Table 3 presents a sample of the annual mean of several pollutants in selected urban centers. The U.S. Environmental Protection Agency has set primary and secondary standards for several pollutants known as *criteria pollutants* (Table 4).

Table 3 Annual Median Concentrations for TSP, NO_2, O_3, and CO for 1979[a]

Location	Concentration			
	$\mu g/m^3$			mg/m^3

Odorants are also objectionable in occupied spaces. In many cases (see Chapter 40 of the 1991 ASHRAE *Handbook—Applications*), equipment that removes odorants also removes some nonodorous gases. The engineer must cope with existing pollution by selecting equipment that provides clean air, and reduce pollution by providing adequate controls to accompany the design. This includes selecting the appropriate equipment for satisfactory combustion, as well as controls that enable the operator to run the equipment according to good practice and applicable air pollution ordinances. When dealing with industrial contaminants, the engineer must design local exhaust systems that minimize the removal of useful materials and provide collection equipment that reduces the amount of material discharged to the atmosphere as required by good practice and existing codes and standards.

RADIOACTIVE AIR CONTAMINANTS

Radioactive contaminants (Jacobson and Morris 1976-77) can be particulate or gaseous and are similar to ordinary industrial contaminants. A major source of airborne radioactive exposure to the population is radon from soil gas. Many radioactive materials would be chemically toxic if present in high concentrations; however, in most cases, the radioactivity necessitates limiting their concentration in air.

Most radioactive air contaminants affect the body when they are absorbed and retained. This is known as the *internal radiation hazard.* Inert gases may be hazardous because the whole body comes in contact with radiation from the gas in the air that surrounds it. These gases are, therefore, *external radiation hazards.* Particulate contaminants may settle to the ground, where they contaminate plants and eventually enter the food chain and the human body. Deposited material on the ground increases external radiation exposure. However, except for fallout from nuclear weapons or a serious reactor accident, such exposure is insignificant.

Radioactive air contaminants can emit alpha, beta, or gamma rays. The alpha rays have very low penetrating power and present no hazard, except when the material is deposited inside or on the body. Beta rays are somewhat more penetrating and can be both an internal and an external hazard. The penetrating ability of gamma rays depends on their energy, which varies from one type of radioactive element or isotope to another. A distinction should be made between the properties of the radioactive material and the radiation given off by this material. Radioactive particles and gases can be removed from air by devices such as filters and absorption traps, but the gamma radiation from such material is capable of penetrating solid walls. This distinction is frequently overlooked. The amount of radioactive material in air is measured in becquerels per cubic metre (1 becquerel equals 2.702702×10^{-11} curies), while the dose of radiation from deposited material is measured in rads.

Radioactive materials present problems that make them distinctive. The contaminants can generate enough heat to damage filtration equipment or ignite spontaneously. The concentrations at which most radioactive materials are hazardous are much lower than those of ordinary materials; as a result, special electronic instruments that respond to radioactivity must be used to detect these hazardous levels.

Radon is a colorless, odorless, radioactive gas found in all soils in various concentrations. Radon gas primarily enters a house or building through leakage paths in the foundation. Radon can then decay through a succession of decay products, producing metallic ions. These decay products then attach to particles suspended in the air or deposit onto surfaces within an occupied space; they can then be inhaled and deposited in the respiratory tract. The subsequent decay produces alpha particles, which may increase the health risk.

The ventilation engineer faces difficulty in dealing with radioactive air contamination because of the extremely low permissible concentrations for radioactive materials. For certain sensitive industrial plants, such as those in the photographic industry, contaminants must be kept from entering the plant. If radioactive materials are handled inside the plant, the problem is to collect the contaminated air as close to the source as possible, and then remove the contaminant from the air with a high degree of efficiency, before releasing it to the outdoors. Filters are generally used for particulate materials, but venturi scrubbers, wet washers, and other devices can be used as prefilters to meet special needs.

The design of equipment and systems for control of radioactive particulates and gases in nuclear laboratories, power plants, and fuel-processing facilities is a highly specialized technology. Careful attention must be given to the reliability, as well as the contaminant-removal ability of the equipment under the special environmental stresses involved. Various publications of the U.S. Department of Energy can provide guidance in this field.

The basic standards for permissible air concentrations are those of the National Committee on Radiation Protection, published by the National Bureau of Standards as Handbook No. 69. Industries operating under licenses from the U.S. Nuclear Regulatory Commission or state licensing agencies must meet requirements of the Code of Federal Regulations, Title 10, Part 20. Some states have additional requirements.

ATMOSPHERIC POLLEN

Pollen grains discharged by weeds, grasses, and trees (Hewson *et al.* 1967, Jacobson and Morris 1976-77, Solomon and Mathews 1978) (and cause hay fever) have properties of special interest to air-cleaning equipment designers (see Chapter 25 of the 1991 ASHRAE *Handbook—Applications*). Whole grains and fragments transported by air range between 10 and 50 μm; however, some measure as small as 5 μm, and others measure over 100 μm in diameter. Ragweed pollen grains are fairly uniform in size, ranging from 15 to 25 μm. Pollen grains can be removed from the air

more readily than the dust particles prevalent in outdoor air or those produced by dusty processes, since the latter predominate in the size range from 0.1 to 10 μm.

Most grains are hygroscopic and, therefore, vary in weight with the humidity. Illustrations and data on pollen grains are available in botanical literature. Geographical distribution of plants that produce hay fever is also recorded.

The quantity of pollen grains in the air is generally estimated by exposing an adhesive-coated glass plate outdoors for 24 h, then counting calibrated areas under the microscope. Methods are available for determining the number of grains in a measured volume of air, but, despite their greater accuracy, they have not replaced the simpler gravity slide method used for most pollen counts. Counting techniques vary, but daily pollen counts reported in local newspapers during hay fever season usually represent the number of grains found on 0.28 in^2 of a 24-h gravity slide.

Hay fever sufferers may experience the first symptoms when the pollen count is 10 to 25; in some localities, maximum figures for the seasonal peak may approach 1000 for a 24-h period, depending on the sampling and reporting methods used by the laboratory. Translation of gravity counts by special formulas to a volumetric basis (*i.e.*, number of grains per unit volume of air) is unreliable, due to the complexity of the modifying factors. When such information is important, it should be obtained directly by a volumetric instrument. The number of pollen grains per cubic yard of air varies from 2 to 20 times the number found on 1 cm^2 of a 24-h gravity slide, depending on grain diameter, shape, specific gravity, wind velocity, humidity, and physical placement of the collecting plate.

Whole grain pollens are easily removed from the outside air entering a ventilation system with medium efficiency filters selected to remove 99% of particles 10μm and greater. Once they have entered a building, the rapid settling rate of whole grain pollens makes it difficult for further air cleaning to reduce the concentrations of these particles. On resuspension from occupant activities, the whole grain pollens may be broken into particles, which may then be controlled effectively with a high-efficiency filter capable of removing a high percentage of particles a few microns in diameter.

AIRBORNE MICROORGANISMS

Interest in airborne microorganisms and their ability to subsist in different environments increased with the need to assemble and launch space probes under sterile conditions, as well as to prevent cross-infection in hospitals. Methods for contamination control are similar to those used in clean rooms to protect critical manufacturing areas from dust contamination.

Public interest focuses on airborne microorganisms, primarily bacteria, responsible for diseases and infections. However, a variety of airborne microorganisms besides bacteria are of economic significance and can cause product contamination or loss. In the food processing industry, yeast and mold can reduce the shelf life of some products. Refined syrups can be damaged by mold scums. Wild yeast can destroy a batch of beer. Antibiotic yields can be reduced by foreign organisms in the culture mix.

Most microorganisms become airborne by attachment to dust particles. Bacteria from the soil are likely to be spore-formers and are capable of surviving in hostile environments. Other airborne bacteria, especially within closed occupied spaces, often originate from droplet nuclei caused by actions such as sneezing. Concentration of microorganisms in the atmosphere vary from a few to several hundred per cubic foot, depending on many factors. The

Table 5 Sources, Possible Concentrations, and Indoor-to-Outdoor Concentration Ratios of Some Indoor Pollutants

Pollutant	Sources of Indoor Pollution	Possible Indoor Concentration[a]	I/O Concentration Ratio	Location
Carbon monoxide	Combustion equipment, engines, faulty heating systems	100 ppm	>>1	Skating rinks, offices, homes, cars, shops
Respirable particles	Stoves, fireplaces, cigarettes, condensation of volatiles, aerosol sprays, resuspension, cooking	100 to 500 μg/m^3	>>1	Homes, offices, cars, public facilities, bars, restaurants
Organic vapors	Combustion, solvents, resin products, pesticides, aerosol sprays	NA	>1	Homes, restaurants, public facilities, offices, hospitals
Nitrogen dioxide	Combustion, gas stoves, water heaters, driers, cigarettes, engines	200 to 1000 μg/m^3	>>1	Homes, skating rinks
Sulfur dioxide	Heating system	20 μg/m^3	<1	Removal inside
Total suspended particles without smoking	Combustion, resuspension, heating system	100 μg/m^3	1	Homes, offices, transportation, restaurants
Sulfate	Matches, gas stoves	5 μg/m^3	<1	Removal inside
Formaldehyde	Insulation, product binders, particleboard	0.05 to 1.0 ppm	>1	Homes, offices
Radon and progeny	Building materials, groundwater, soil	0.1 to 200 nCi/m^3	>>1	Homes, buildings
Asbestos	Fireproofing	< 10^6 fiber/m^3	1	Homes, schools, offices
Mineral and synthetic fibers	Products, cloth, rugs, wallboard	NA	—	Homes, schools, offices

sampling method for microorganisms has an effect on the measured count. Collection on dry filter paper can cause count degradation because of the dehydration loss of some organisms. Glass impingers may give high counts because agitation can cause clusters to break up into smaller individual organisms. Slit samples may give a more accurate colony count.

When maximum removal of airborne microorganisms is either necessary or desirable, super-interception, high-efficiency particulate air (HEPA) filters are used. These filters create essentially sterile atmospheres and are preferred over chemical scrubbers and ultraviolet radiation that are also used to control airborne microorganisms.

In many situations, total control of airborne microorganisms is not required. For these situations, there are different types of high-efficiency dry media extended surface filters that provide the desired efficiency necessary for certain applications. These filters have lower pressure drops than HEPA filters and can manage or filter out the concerned contaminant.

INDOOR AIR QUALITY

Indoor air quality in residences, offices, and other indoor, nonindustrial environments is a concern (Spengler *et al.* 1982, NRC 1981). Exposure to indoor pollutants can be as important as exposure to outdoor pollutants because a large portion of the population spends up to 90% of their time indoors and because indoor pollutant concentrations are frequently higher than corresponding outdoor pollutant levels.

Characterization of the indoor air quality has been the subject of numerous recent studies. ASHRAE Indoor Air Quality (IAQ) Conference proceedings discuss indoor air quality problems and some practical controls. ASHRAE *Standard* 62-1989 addresses many indoor air quality concerns. Table 5 illustrates the sources, levels, and the indoor-to-outdoor concentration ratio of several pollutants found in indoor environments. Chapter 37 has further information.

CHAPTER 12

ODORS

Sense of Smell 12.1
Sensory Measurement 12.2
Analytical Measurements 12.5
Odor Sources 12.5
Factors Affecting Odors 12.5

VARIOUS factors make odor control a primary consideration in ventilation engineering: (1) modern buildings permit less air infiltration through walls and have more indoor sources of odors associated with building materials, furnishings, and office equipment; (2) outdoor air, previously clean and odor-free, is often polluted; and (3) high energy costs have caused a reduction in ventilating rates at a time when requirements for a relatively odor-free environment are greater than ever.

This chapter reviews how odoriferous substances are perceived and controlled. Chapter 40 of the 1991 ASHRAE *Handbook—Applications* has more information on control methods.

SENSE OF SMELL

Olfactory Stimuli

Among organic substances, those with molecular weights greater than 300 are generally odorless. However, some substances with molecular weights less than 300 are such potent olfactory stimuli that they can be perceived at concentrations too low to be detected directly by existing instruments. Trimethylamine, for example, can be recognized by a human observer at a concentration of about 10^{-4} ppm. Table 1 shows threshold concentrations for selected compounds. These threshold values are not precise numbers and may vary by more than one order of magnitude. The American Industrial Hygiene Association (1989) provides a large, critically evaluated list of threshold values, which documents this point.

Olfactory sensitivity often makes it possible to detect and eliminate potentially harmful substances at concentrations below dangerous levels. Often foul-smelling air is also assumed to be unhealthy. When symptoms such as nausea, headache, and loss of appetite are caused by an unpleasant odor, it may not matter whether the air is toxic. The magnitude of the symptoms is related to the magnitude of the odor. Even a room with a low but recognizable odor can arouse uneasiness among occupants. Cometto *et al.* (1987) review sensory irritation and its relation to indoor air pollution.

Anatomy and Physiology

The olfactory receptors lie in the *olfactory cleft*, which is high in the nasal passages. The surrounding tissue contains other diffusely distributed receptors—free nerve endings that also respond to airborne vapors. These receptors of common chemical sense mediate the tickling, burning, cooling, and occasionally, painful sensations that accompany olfactory sensations. Ammonia stimulates these free nerve endings, as do other substances that have any degree of pungency. Thus, olfaction and the common chemical sense operate as a single perceptual system (Cain 1976).

About 5-million olfactory neurons, a small cluster of nerve cells inside the nasal cavity above the bridge of the nose, determine whether the air is odoriferous. These olfactory receptors are connected by a nerve fiber into the olfactory bulb of the brain. The bulb passes information it receives from the receptors to various central structures of the brain, including an area called the *seat of emotion*. One sniff of an odorant can often evoke a complex, emotion-laden memory, such as a scene from childhood.

Hormonal factors, which often mediate emotional states, can modulate olfactory sensitivity. Although the evidence is not uniformly compelling, research has found that (1) the sensitivity of women varies during the menstrual cycle, reaching a peak just before and during ovulation (Schneider 1974); (2) women are generally more sensitive than men, but this difference only emerges around the time of sexual maturity (Koelega and Koster 1974); (3) sensitivity is altered by certain diseases (Schneider 1974); and (4) various hormones and drugs (*e.g.*, estrogen and alcohol) alter sensitivity (Schneider 1974, Engen *et al.* 1975). Other factors that may affect olfactory perception include the olfactory acuity of an individual, the magnitude of the flow rate toward the olfactory receptors, the temperature, and the relative humidity. Humans are able to perceive over 4000 different odors, yet individuals are able to name only a small number of odors (Ruth 1986).

Table 1 Odor Threshold of Selected Gaseous Air Pollutants

Pollutant	Odor Threshold, mg/m³	Pollutant	Odor Threshold, mg/m³
Acetaldehyde	1.2	Hydrogen cyanide	1
Acetone	47	Hydrogen fluoride	2.7
Acetonitrile	>0	Hydrogen sulfide	0.007
Acrolein	0.35	Mercury	∞
Acrylonitrile	50	Methanol	130
Allyl chloride	1.4	Methyl chloride	595
Ammonia	33	Methylene chloride	750
Benzene	15	Nitric oxide	>0
Benzyl chloride	0.2	Nitrogen dioxide	51
2-Butanone (MEK)	30	Ozone	0.2
Carbon dioxide	∞	Phenol	0.18
Carbon monoxide	∞	Phosgene	4
Carbon disulfide	0.6	Propane	1800
Carbon tetrachloride	130	Sulfur dioxide	1.2
Chlorine	0.007	Sulfuric acid	1
Chloroform	1.5	Tetrachloroethane	24
p-Cresol	0.056	Tetrachloroethylene	140
Dichlorodifluromethane	5400	o-Toluidene	24
Dioxane	304	Toluene	8
Ethylene dichloride	25	Toluene diisocyanate	15
Ethylene oxide	196	1,1,1 Trichloroethane	1.1
Formaldehyde	1.2	Trichloroethylene	120
n-Heptane	2.4	Vinyl chloride monomer	1400
Hydrogen chloride	12	Xylene	2

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment.

SENSORY MEASUREMENT

Sensory measurements yield data under one of the following categories:

- Nominal data that indicate different categories, but not in any order of magnitude; for example, the numbers used in a team or panel of odor sniffers.
- Ordinal data that fall into two or more classes belonging to an ordered series, *i.e.*, the odor is either slight, moderate, or strong.
- Interval data that are placed in ordered classes separated by a meaningful measure or interval between them, for example, first, second, third.
- Ratio data that indicate how many times a quantity is larger than a reference quantity, for example, temperature scales (Meilgaard *et al.* 1987).

The odor sensation has four odor components or attributes: detectability, intensity, character, and hedonic note. Detectability or threshold is the minimum concentration of an odorant that provoked detection of the odorant to some predetermined segment of the population. Two types of thresholds exist: the *detection* threshold and the *recognition* threshold. The detection threshold is the lowest level that elicits response by a segment of the population. If that segment is 50%, the detection threshold is denoted by ED_{50}. Such thresholds can, however, be attributed to 100%, which includes all olfactory sensitivities, or to 10%, which refers only to the most sensitive segment of the population. Threshold values are not physical constants; rather they are statistical measurements of best estimates.

Intensity is a quantitative aspect of a descriptive analysis, stating the degree to which a characteristic odor is present. Intensity of the perceived odor is, therefore, the strength of the odoriferous sensation. Detection threshold values and, most often, odor intensity determine the need for indoor odor controls.

Odor character defines the odor as similar to some familiar smell, *e.g.*, fishy, sewer, flowery, and the like. Hedonics, or the hedonic tone of an odor, is the degree to which an odor is perceived as pleasant or unpleasant. Hedonic judgments include both *category* judgments (pleasant, neutral, unpleasant) and a *magnitude* judgment (very unpleasant, slightly pleasant) and so on.

Important questions are (1) What is the minimum concentration of odorant necessary to produce a just-detectable odor? and (2) How does perceived odor magnitude grow with concentration above the threshold? No universal way has been accepted to measure either the threshold or suprathreshold magnitude. However, certain guidelines and conventions simplify the choice of methods.

Olfactory acuity. The olfactory acuity of the population is normally distributed—that is, most people have an average ability to smell substances or to respond to odoriferous stimuli, a few people are very sensitive or hypersensitive, and a few others are insensitive, including some who are totally unable to smell, *i.e.*, they are anosmic. The segment of the population with average ability to smell varies between 90% and 96%. In addition, the olfactory acuity of an individual varies as a function of the odorant. For instance, repeated exposure to an odorant may lead to anosmia (absence of the sense of smell) only to that odorant.

Threshold. The perception of weak odoriferous signals is probabilistic; at one moment the signal may make a discernible impact, at the next moment it may not. One reason for this phenomenon is moment-to-moment variability in the number of molecules striking the receptors; another is the variability in which receptors are contacted. Other important sources are a person's state of readiness or fatigue. The combined effect of these various sources prevents an individual from perceiving an odor during the entire time of the stimulus. The objective of dilution to detection (recognition) threshold values is to find the largest number of dilutions that would cause half of the panelists to detect (recognize) the odor.

Measurement of odor attributes is complex. Several methods, such as those described by Dravnieks (1979) and NAS (1979), are used to measure odor threshold numbers. ASTM STP 434 (1982) describes the forced choice dynamic olfactometer method. The most frequently used dynamic olfactometer has six ports or sets. Within each port, three glass sniffers are arranged in a circular pattern to achieve blind presentation to the subject. Two of the sniffers supply nonodoriferous air, and the third sniffer provides the diluted odorous air. The subject is asked to identify or guess the sniffer with the odoriferous air.

The odoriferous air is supplied to each port at various levels of dilution. Samples are diluted either by compressed air or by room air using a peristaltic pump and are presented in decreasing levels of dilution. The dilution factors from port one to port six are 3600x, 1200x, 400x, 45x, and 15x (IITRI 1980). The odorant is presented in increasing rather than random order because exposure to one of the higher concentrations can temporarily impair the ability to detect weaker concentrations.

The subject can be tested with additional ascending series. The concentration of interest in each series is the lowest in the string of three correct detections. The geometric mean taken across the various series provides a good index of the subject's threshold. In a similar manner, the geometric mean taken across several subjects provides a good index of the threshold for a group.

Three issues of technical and practical importance are: (1) rate of airflow to the sniffers, (2) size of panel, and (3) design of the sniffers. Presently, the flow rate varies from 8 to 50 mL/s, and, in some cases, much greater. Present test practices use as few as five panelists or as many as ten. While a small panel is representative only of itself, too large a panel is difficult to manage. A panel of ten provides statistically sound data.

Finally, the sniffers used with current dynamic olfactometers are small glass ports that allow the panelist to sniff as close or as far as desired. An alternative design is a cup arrangement that requires the panelist to insert the nose into the cup and eliminates variation in the dilution between the delivered air and the air actually sniffed by the panelist.

In all sensory testing, it is necessary to guard against subtle biases and clues that may influence results. Also, adequate statistical procedures should be used to detect biases such as whether there is a reliable psychophysical difference between odorants, between means of air sampling, etc.

For more details regarding psychophysical procedures, ways to sample odoriferous air, handling samples, means of stimulus presentation, and statistical procedures, consult ASTM STP 434.

Suprathreshold intensity. The relation between *perceived odor magnitude* S and *concentration* C conforms to a power function

$$S = kC^n \quad (1)$$

This exemplifies the psychophysical power law, also called Stevens' law (1957). The law applies throughout the sensory realm and has almost completely replaced the Weber-Fechner logarithmic law in modern psychophysics. In the olfactory realm, the exponent n of the power function is less than 1.0. Accordingly, a given percentage change in concentration causes a smaller percentage change in perceived magnitude. The size of the exponent varies from one odorant to another, ranging from less than 0.2 to about 0.7 (Cain and Moskowitz 1974), which has important consequences for malodor control. An exponent of 0.7 implies that in order to reduce perceived intensity by a factor of 5, for instance, concentration must be reduced by a factor of 10. An exponent of 0.2 implies that a fivefold reduction in perceived magnitude can be achieved by slightly more than a three-thousandfold reduction in concentration.

Of the various ways to scale perceived magnitude, a *category scale*, which can be either number or word categorized, is commonly used. Numerical values on this scale do not reflect ratio relations among odor magnitudes; *i.e.*, a value of 2 does not represent a perceived magnitude twice as great as a value of 1. Table 2 gives four examples of category scales (Meilgaard *et al.* 1988).

Although category scaling procedures can be advantageous in field situations, *ratio scaling* techniques are used frequently in the laboratory (Cain and Moskowitz 1974). Ratio scaling procedures require observers to assign numbers proportional to perceived magnitude. If the observer is instructed to assign the number 10 to one concentration and a subsequently presented concentration seems three times as strong, the observer calls it 30; if it seems one-half as strong, the observer assigns it 5, etc. This ratio scaling procedure, called *magnitude estimation*, was used to derive the power function for butanol (Figure 1). Equation (1) in this case becomes $\log S = n \log C + \log k$, which has the form $y = ax + b$. By means of this transformation, the exponent becomes the slope of the line. The function for butanol conforms to the equation $S = 0.26\, C^{0.66}$, which represents a consensus of results obtained in various laboratories (Moskowitz *et al.* 1974). According to this equation, a concentration of 250 ppm has a perceived magnitude of 10. This corresponds to *moderate intensity*. A concentration near threshold (2 to 5 ppm) has a perceived magnitude of about 0.5.

A third way to measure suprathreshold odor intensity is to match the intensity of odorants. An observer can be given a concentration series of a matching odorant (*e.g.*, 1-butanol) to choose the member that matches most closely the intensity of an *unknown* odorant. The matching odorant can be generated by a relatively inexpensive olfactometer such as that shown in Figure 2 (Dravnieks 1975). Figure 3 shows, in logarithmic coordinates, functions for various odorants obtained by the matching method (Dravnieks and Laffort 1972). The left-hand ordinate expresses intensity in terms of concentration of butanol, and the right-hand ordinate expresses intensity in terms of perceived magnitude. The two ordinates are related by the function in Figure 1, the standardized function for butanol. The matching method illustrated here has been incorporated into ASTM E544-75, *Practice for Referencing Suprathreshold Odor Intensity*.

A National Academy of Sciences document (NAS 1979) elaborates on attitudes regarding odor units. The objection to the odor unit is associated with the fact that odor is a sensation not a substance. Here is an example of the concept of odor concentration: if 1 ft^3 of odorous air were diluted with N ft^3 of fresh air to reach the threshold value, then the odoriferous sample has an odor concentration of N units/ft^3. Confusion occurs when other dimensions for volume are used. In response to this confusion, ASTM defined the dimensionless factor Z for the dilution to detection threshold: Z equals the ratio of the odorant concentration C divided by its concentration at threshold C_{thr} (ASTM 1978). Note: Z numerically equals the odor units per cubic foot.

The following example from the NAS document illustrates the concepts: $Z = 1000$ when one volume of odorous sample requires 1000 volumes to reach the dilution threshold. Furthermore, if the

Table 2 Examples of Category Scales

Number Category		Word Category	
Scale I	Scale II	Scale I	Scale II
0	0	None	None at all
1	1	Threshold	Just detectable
2	2.5	Very slight	Very mild
3	5	Slight	Mild
4	7.5	Slight-moderate	Mild-distinct
5	10	Moderate	Distinct
6	12.5	Moderate-strong	Distinct-strong
7	15	Strong	Strong

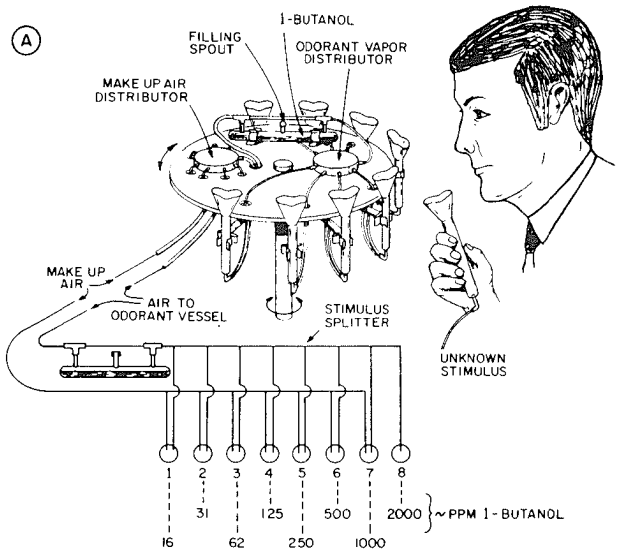

Fig. 2 Panelist Using Dravnieks Binary Dilution Olfactometer

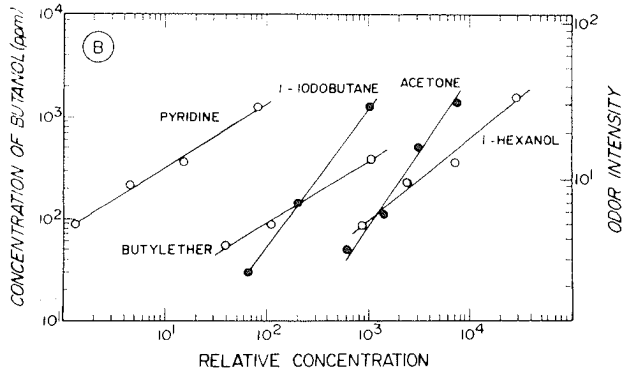

Fig. 3 Matching Functions Obtained with Dravnieks Olfactometer
(Dravnieks and Laffort 1972, Cain 1978)

sampled air is emitted at 50 m^3/min, the odorous emission rate is 1000 × 50 = 50,000 m^3/min, which is the clean air demand of the odorous emission. This value is equivalent to odor units per minute after conversion from cubic meters to cubic feet. The engineer should be aware of the present understanding on this unit and deal accordingly with existing and proposed regulations on odor measurement and removal.

Odor units. According to ASTM D135, Standard Definitions of Terms Relating to Atmospheric Sampling and Analysis, odor concentration can be expressed as the number of unit volumes that a unit volume of odorous sample occupies when diluted to the odor threshold with nonodorous air. If a sample of odorous air can be reduced to threshold by a tenfold dilution with pure air, the concentration of the original sample is said to be 10 odor units. Hence, odor units are equivalent to multiples of threshold concentrations.

Odor units are used widely to express legal limits for emission of odoriferous materials. For example, the law may state that a factory operation may not cause the ambient odor level to exceed 15 odor units. It should be recognized that odor units are *not* units of perceived magnitude. For every odorant, odor units and parts-per-million are proportional. The proportionality constant varies from one odorant to another, depending on the number of ppm needed to evoke a threshold response. Since perceived odor magnitude does not grow proportionally with concentration expressed in ppm, it cannot grow proportionally with concentration expressed in odor units. According to the results of psychophysical scaling, a sample of 20 odor units is always perceived as less than twice as strong as a sample of 10 odor units. Moreover, since the rate of growth of the psychophysical function varies from one odorant to another, samples of two odorants, each at 20 odor units, may have unequal perceived intensities.

Although odor units are not equivalent to units of perceived magnitude, they can be useful. Most indoor and outdoor contaminants are complex mixtures; the actual concentration of the odoriferous portion of a sample cannot be expressed with certainty. Thus, the odor unit is a useful measure of *concentration* when evaluating, for example, the efficiency of a filter or ventilation system.

Odor acceptability. The acceptability or pleasantness of an odor can be measured psychophysically in the same way as odor intensity. Either ratio or category scaling procedures can be adapted to this task.

Odors do not always cause adverse reactions. Products are manufactured to elicit favorable responses. Acceptance tests may involve product comparison (frequently used in the perfume industry) or a hedonic scale (Figure 4). The premise of acceptance tests is that the larger the segment of subjects accepting the odor, the better the odor. A hedonic scale that allows for negative as well as positive responses is likely to be more responsive to the question of how acceptable the odor is.

A given odor is not likely to be perceived as acceptable or unacceptable by all those potentially exposed. Acceptability of a given odor by a given person is due to a complex combination of associations and is not simply a characteristic of the odor itself (Beck and Day 1991).

Odor quality. The quality or character of an odor is difficult to assess quantitatively. A primary difficulty is that odors can vary along many dimensions. One way to assess quality is to ask panelists to judge the similarity between a test sample and various reference samples, using a 5-point category scale. For certain applications, reference odorants can be chosen to represent only that portion of the qualitative range relevant to the odor problem under investigation (*e.g.*, animal odors). Another procedure is to ask panelists to assess the degree of association between a test sample's quality and certain verbal descriptors (*e.g.*, sweaty, woody, chalky, sour).

The number of odorant descriptors and the descriptors to be used have been subjects of disagreement (Harper *et al.* 1968). The number of descriptors varies from a minimum of seven (Amoore 1962) to as many as 830 used by an ASTM subcommittee. An atlas of odor characters, containing 146 descriptors, was compiled for 180 chemicals by ASTM (1985).

An odor can be characterized either by an open-ended word description or by multidimensional scaling. Multidimensional scaling is based on similarity/dissimilarity judgments to a set of standard odors or to various descriptors.

In some instances, the interest merely may be whether an odor's quality has changed as a result of some treatment (*e.g.*, use of a bacteriostat). Under these circumstances, samples of air taken before and after treatment can be compared directly (using a simple scale of similarity) or indirectly (with appropriate verbal descriptors).

Olf unit. Indoor air quality scientists have not successfully resolved complaints associated with pollution in offices, schools, and other nonindustrial environments. Customarily, complaints are attributed to elevated pollutant concentrations; frequently, however, such high concentrations are not found indoors, yet complaints persist. The lack of an apparent cause and effect relationship between complaint and elevated indoor pollutant concentrations is sometimes known as the *sick building syndrome.*

Assuming that the inability to find a difference between air pollutant levels in buildings with registered complaints and in buildings without any complaints is due to inadequacies of prevailing

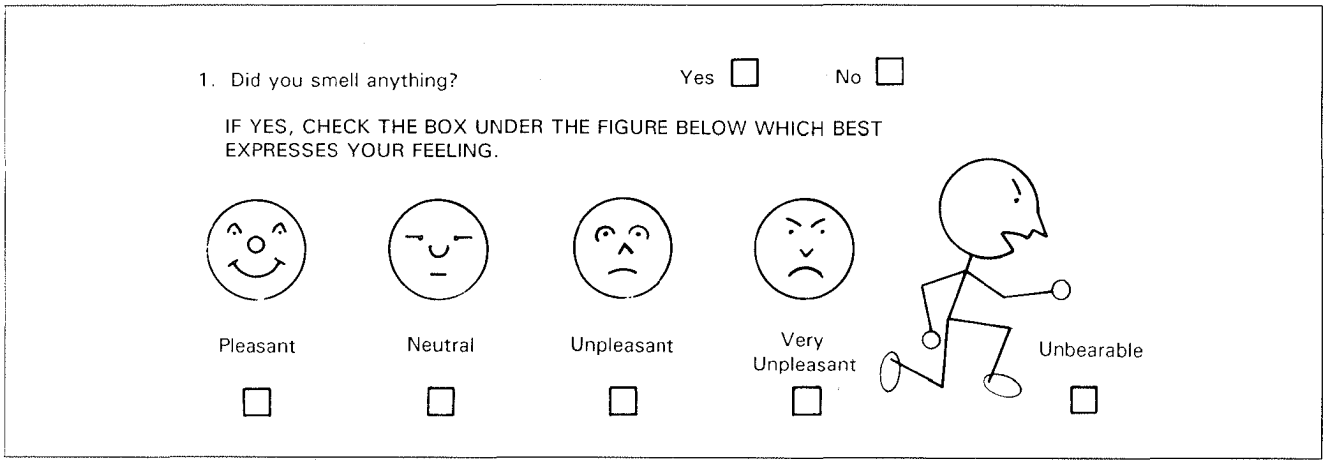

Fig. 4 Hedonic Scale Used for Evaluation of Odors in Population Surveys

measurement techniques, Fanger and others changed the focus from chemical analysis to sensory analysis (Fanger 1987, 1988). Fanger quantified air pollution sources by comparing them with a well-known source—a sedentary person in thermal comfort. A new unit, the olf, was introduced. An olf is defined as the emission rate of air pollutants (bioeffluents) from a standard person.

To use this unit, Fanger generated curves that relate the percentage of persons dissatisfied with the emissions of one person in a chamber as a function of fresh air ventilation rate, obtaining the following expression:

$$D = 395 \exp(-1.83\, q^{0.26}) \text{ for } q \geq 0.332$$

$$D = 100 \text{ for } q < 0.322$$

where

D = percentage dissatisfied persons
q = ventilation-emission ratio, L/s × olf

Such curves can be used in the study of indoor nonindustrial environments. A large number of judges (over 50) is used in a study. They visit the test environment under three different conditions: when the test indoor environment is (1) unoccupied and unventilated; (2) unoccupied but ventilated; and (3) occupied and ventilated. These measurements help in quantifying the sensory impact from such sources as building materials, the ventilation system, and occupant activity. Results are obtained by analyzing the responses to a questionnaire (Fanger *et al.* 1988).

ANALYTICAL MEASUREMENTS

More exact performance data on the control of specific odorants can be obtained using suitable analytical methods (Kaiser 1963). Detectors exist that permit detection of substances in amounts of about one nanogram. Since air usually contains many minor components, gas-chromatographic separation of the components must precede detection. Since odor thresholds for some compounds are low, a preconcentration of the minor components is necessary. Preconcentration is usually achieved by adsorption or absorption by a stable, sufficiently nonvolatile material, followed by thermal desorption or extraction.

Mass spectrometry can be used with gas chromatography to identify constituents of complex mixtures. The chromatograph resolves a mixture into its constituents, and the spectrometer yields data (mass spectra) that permit specification of chemical structure.

Several detectors are sufficiently sensitive and specific to detect resolved components. Hydrogen flame ionization detectors respond adequately and almost mass-proportionally to almost all organic compounds. Flame-photometric detectors can pinpoint, with equal sensitivity, compounds that contain sulfur; many sulfur compounds are strongly odorous and are of interest in odor work. A Coulson conductometric detector is specifically and adequately sensitive to ammonia and organic nitrogen compounds. Thermal conductivity detectors are generally not sensitive enough for analytical work on odors.

Airborne volatile organic compounds (VOCs) cause odors, but the correlation between indoor VOC concentrations and odor complaints in indoor environments is poor. An ACGIH document (1991), and others review the state of the art for sampling and analysis of VOCs in indoor air. The nose is the most sensitive instrument, however, and it can perceive odors from complex mixtures of VOCs at low indoor concentrations.

Frequently, a sniffing port (Dravnieks and O'Donnell 1971, Dravnieks and Krotoszynski 1969) is installed in parallel with the detector(s). Part of the resolved effluent exhausts through the port and allows the components that are particularly odorous or carry some relevant odor quality to be annotated. Usually, only a fraction of all observed components exhibit odors—particularly those of interest in odor evaluation. A change in odorant concentration indicated by detector responses may result from odorant removal treatment by ventilation or another process (Dravnieks *et al.* 1971). Odor control may not influence all odorant concentrations to the same extent, and new odorants may have appeared.

Since the physicochemical correlates of olfaction are poorly understood, no simple analytical means to predict the perceived quality and intensity of an odorant exists. Moreover, since acceptability of an odorant depends strongly on context, it is unlikely that analytical instruments will supplant human evaluation.

ODOR SOURCES

Outdoor sources of odors include automotive exhaust (emitting, among others, organic compounds); hazardous waste sites (organic compounds); wastewater treatment, composting, and refuse facilities (hydrogen sulfide, ammonia, and organic compounds); chemicals emitted from printing, paint, synthetics (organic compounds); and other stationary and mobile sites. Odors emitted by sources in the ambient environment eventually enter the indoor environment.

Indoor sources also emit odors. Such sources include cigarette and other tobacco product smoke, which includes particulate matter and volatile organic compounds; bathrooms (ammonia and other odors); building materials, such as adhesives, paints, processed wood, carpets, caulks, and other volatile organic compounds; consumer products, such as food, bathroom products, hobbies materials, paint sprays, personal care products, drapes, upholstery, and other furnishings (VOCs); reproduction and print shops in office buildings (ozone and organics).

Odors may also be emitted from wetted air-conditioning coils. Putrefaction of animal and vegetable matter also contribute to indoor odors. Several studies have been performed to measure the emission rates of organic compounds from indoor sources (Moschandreas and Gordon 1991), but no such efforts have been made to measure indoor odor emissions. Chapter 40 in the 1991 ASHRAE *Handbook—Applications* gives further information on contaminant sources and generation rates.

FACTORS AFFECTING ODORS

Humidity and Temperature

Odor perception of cigarette smoke (suspension of tobacco tar droplets plus vapor) and pure vapors is affected by temperature and humidity. An increase in humidity, at constant dry-bulb temperature, lowers the intensity level of cigarette smoke odor, as well as that of pure vapors (Kerka and Humphreys 1956, Kuehner 1956). This effect is more pronounced for some odorants than for others. An increase in temperature at constant specific humidity lowers the odor level of cigarette smoke slightly. Adaptation to odors takes place more rapidly during the initial stages of exposure. While the perceptible odor level of cigarette smoke decreases with exposure time, irritation to the eyes and nose generally increases. The irritation is greatest at low relative humidities.

To keep odor perception and irritation at a minimum, the air-conditioned space should be operated at about 45 to 60% rh. Since

temperature has only a slight effect on odor level at constant specific humidity, it generally can be ignored; temperature should be maintained at conditions desired for comfort or economy.

Sorption and Release of Odors

Frequently, spaces develop normal occupancy odor levels long after occupancy has ceased. This results from sorption of odors on the furnishings during occupancy, with later desorption. This is observed when furnaces or radiators, after a long shutdown, are heated at winter startup. It also can be observed when evaporator coils warm up. Hubbard *et al.* (1955) tested the odorant sorption-release of cotton, wool, nylon, rayon, and fir wood. As a guide to correcting the sorbed odor situation, the rate of desorption can be decreased by decreasing temperature and relative humidity, and increased (as for cleaning) by the reverse.

Smoke, cooking, and body odor perception decreases as humidity increases. Where the odor source is intrinsic with the materials, as in linoleum, paint, rubber, and upholstery, reducing relative humidity is beneficial (Kuehner 1956) and decreases the rate of odor release. Quantitative values should not be used without considering the sorption-desorption phenomenon.

Dilution of Odors by Ventilation

Cain *et al.* (1983, 1987) compared occupancy odor with smoke odor by relating perceived odor intensity and odor acceptability during smoking and nonsmoking under controlled chamber conditions. When smoking took place, they found that the odor intensity was nearly five times as high as the odor intensity perceived under severe occupancy conditions (hot, humid, and low ventilation) but with no smoking. This study also determined that the ventilation rate required to control occupancy odor to a criterion of 80% acceptance is 17 cfm; for tobacco smoke odor, it is 53 cfm.

CHAPTER 13

MEASUREMENT AND INSTRUMENTS

Terminology 13.1
Error Analysis 13.3
Temperature Measurement 13.4
Pressure Measurements 13.10
Velocity Measurement 13.12
Flow Rate Measurement 13.16
Electric Measurement 13.19
Humidity Measurement 13.20
Sound and Vibration Measurement 13.23
Combustion Analysis 13.25
Rotative Speed Analysis 13.26
Thermal Comfort Measurement 13.26
Moisture Content and Transfer Measurement 13.27
Heat Transfer through Building Materials 13.28
Air Infiltration and Airtightness Measurement 13.28
Air Contaminant Measurement 13.29
Lighting Measurement 13.29
Data Recording 13.29

HEATING, refrigerating, and air-conditioning engineers and technicians require instruments for laboratory and field work. Precision is more essential in the laboratory (where research and development are undertaken) than in the field (where acceptance and adjustment tests are conducted). This chapter describes some of these instruments.

TERMINOLOGY

The following definitions are generally accepted.

Accuracy. The capability of an instrument to indicate the true value of measured quantity. This is often confused with inaccuracy, which is the departure from the true value into which all causes of error are lumped, *e.g.*, hysteresis, nonlinearity, drift, temperature effect, and other sources of error.

Amplitude. The magnitude of variation in an alternating quantity from its zero value.

Average. The sum of a number of values divided by the number of values.

Band width. The range of frequencies over which a given device is designed to operate within specified limits.

Bias. The tendency of an estimate to deviate in one direction from a true value (a systematic error).

Calibration. (1) The process of comparing a set of discreet magnitudes or the characteristic curve of a continuously varying magnitude with another set or curve previously established as a standard. Deviation between indicated values and their corresponding standard values constitutes the correction (or calibration curve) for inferring true magnitude from indicated magnitude thereafter; (2) the process of adjusting an instrument to fix, reduce, or eliminate the deviation defined in (1).

Calibration curve. (1) The path or locus of a point that moves so that its coordinates on a graph correspond to values of input signals and output deflections; (2) the plot of error versus input (or output).

Confidence. The degree to which a statement (measurement) is believed to be true.

Deviate. Any item of a statistical distribution that differs from the selected measure of control tendency (average, median, mode).

Deviation, standard. The square root of the average of the squares of the deviations from the mean (root-mean-square) deviation. A measure of dispersion of a population.

Distortion. An unwanted change in wave form. Principal forms of distortion are inherent nonlinearity of the device, nonuniform response at different frequencies, and lack of constant proportionality between phase-shift and frequency. (A wanted or intentional change might be identical, but is called *modulation.*)

Drift. A gradual, undesired change in output over a period of time, unrelated to input, environment, or load. Drift is gradual. If variation is rapid, the fluctuation is referred to as cycling.

Dynamic error band. Band refers to the spread or band of output-amplitude deviation incurred by a constant amplitude sine wave as its frequency is varied over a specified portion of the frequency spectrum (see Static Error Band).

Error. The difference between the true or actual value to be measured (input signal) and the indicated value (output) from the measuring system. Errors can be systematic or random.

Error, accuracy. See Error, Systematic.

Error, fixed. See Error, Systematic.

Error, instrument. An instrument reading that includes random or systematic errors.

Error, mean square, or **RMS.** An accuracy statement of a system comprised of several items. For example, a laboratory potentiometer, volt box, null detector, and reference voltage source have individual accuracy statements assigned to them. These errors are generally independent of one another, so a system comprised of these units displays an accuracy given by the square root of the sum of the squares of the individual limits of error. For example, four individual errors of 0.1% yield a calibrated accuracy of 0.4% but an RMS error of only 0.2%.

Error, measurement. The result of a correction that is applied for any system error.

Error, precision. See Error, Random.

Error, probable. An error with a 50% chance of occurrence. A statement of probable error is of little value.

Error, random. A statistical error caused by chance and not recurring. This term is a general category for errors that can take values on either side of an average value. To describe a random error, its distribution must be known.

Error, systematic. A persistent error not caused by chance. Systematic errors are causal. A systematic error is likely to have the same magnitude and sign for every instrument constructed with the same components and procedures. Errors in calibrating equipment cause systematic errors, because all instruments calibrated are biased in the direction of the calibrating equipment error. Voltage and resistance drifts with time are generally in one direction and are classed as systematic errors.

Frequency response (flat). The portion of the frequency spectrum over which the measuring system has a constant value of amplitude response and a constant value of time lag. Input signals that have frequency components within this range are indicated by the measuring system (without distortion).

The preparation of this chapter is assigned to TC 1.2, Instruments and Measurements.

Hysteresis. The summation of all effects, under constant environmental conditions, which causes output of an instrument to assume different values at a given stimulus point when that point is approached first with increasing stimulus and then with decreasing stimulus. Hysteresis includes backlash. It is usually measured as a percent of full scale when input varies over the full increasing and decreasing range. In instrumentation, hysteresis and dead band are similar quantities.

Linearity. The straight-lineness of the transfer curve between an input and an output—that condition prevailing when output is directly proportional to input (see Nonlinearity).

Loading error. A loss of output signal from a device caused by a current drawn from its output. It increases the voltage drop across the internal impedance where no voltage drop is desired.

Mean. See Average.

Median. The middle value in a distribution, above and below which lie an equal number of values.

Noise. Any unwanted disturbance or spurious signal that modifies the transmission, measurement, or recording of desired data.

Nonlinearity. The prevailing condition (and the extent of its measurement) under which the input-output relationship fails to be a straight line, which is known as the input-output curve, transfer characteristic, calibration curve, or response curve. Nonlinearity is measured and reported in several ways, and the way, along with the magnitude, must be stated in any specification.

Minimum-deviation-based nonlinearity. The maximum departure between the calibration curve and a straight line drawn to give the greatest accuracy; expressed as a percent of full-scale deflection.

Slope-based nonlinearity. The ratio of maximum slope error anywhere on the calibration curve to the slope of the nominal sensitivity line; usually expressed as a percent of nominal slope.

Most variations beyond these two definitions result from the many ways in which the straight line can be arbitrarily drawn. All are valid as long as construction of the straight line is explicit.

Population. A group of individual persons, objects, or items from which samples may be taken for statistical measurement.

Precision. The repeatability of measurements of the same quantity under the same conditions, not a measure of absolute accuracy. The precision of a measurement is used here to describe the relative tightness of the distribution of measurements of a quantity about their mean value. Therefore, precision of a measurement is associated more with its repeatability than its accuracy. It combines uncertainty caused by random differences in a number of identical measurements and the smallest readable increment of the scale or chart. Precision is given in terms of deviation from a mean value.

Primary calibration. A calibration procedure in which the instrument output is observed and recorded, while the input stimulus is applied under precise conditions—usually from a primary external standard traceable directly to the National Institute of Standards and Technology.

Range. A statement of the upper and lower limits between which an instrument's input can be received and for which the instrument is calibrated.

Reliability. The probability that an instrument's repeatability and accuracy will continue to fall within specified limits.

Repeatability. See Precision.

Reproducibility. In instrumentation, the closeness of agreement among repeated measurements of the output for the same value of input made under the same operating conditions over a period of time, approaching from both directions; it is usually measured as a nonreproducibility and expressed as reproducibility in percent of span for a specified time period. Normally, this implies a long period of time, but under certain conditions, the period may be a short time during which drift may not be included. Reproducibility includes hysteresis, dead bank, drift, and repeatability. Between repeated measurements, the input may vary over the range, and operating conditions may vary within normal operating conditions.

Resolution. The smallest change in input that produces a detectable change in instrument output. Resolution differs from precision in that it is a psychophysical term referring to the smallest increment of humanly perceptible output (rated in terms of the corresponding increment of input). Either or both the precision and resolution may be better than the accuracy. An ordinary six-digit (or dial) instrument has a resolution of one part per million (ppm) of full scale; however, it is possible that the accuracy is no better than 25 ppm (0.0025%). Note that the practical resolution of an instrument cannot be any better than the resolution of the indicator or detector—whether it is an internal or external device.

Scale factor. (1) The amount by which a measured quantity must change to produce unity output; (2) the ratio of real to analog values.

Sensitivity. The property of an instrument that determines scale factor. The word is often short for maximum sensitivity or the minimum scale factor with which an instrument can respond. The minimum input signal strength required to produce a desired value of output signal (*e.g.*, full scale or unit output or the ratio of output to input values).

Sensitivity inaccuracy. The maximum error in sensitivity displayed as a result of the summation of the following: frequency response; attenuator inaccuracy; hysteresis or dead-band; amplitude distortion (sensitivity nonlinearity); phase distortion (change in phase relationship between input signal and output deflection); and gain instability. Only by taking into account all these factors can nominal sensitivity, as indicated by the numeral on the attenuator readout, be discounted for accurate interpretation.

Stability. (1) Independence or freedom from changes in one quantity as the result of a change in another; (2) the absence of drift.

Static error band. (1) The spread of error present if the indicator (pen, needle) stopped at some value, *e.g.*, at one-half of full scale. It is normally reported as a percent of full scale; (2) a specification or rating of maximum departure from the point where the indicator must be when an on-scale signal is stopped and held at a given signal level. This definition stipulates that the stopped position can be approached from either direction in following any random waveform. Therefore, it is a quantity that includes hysteresis and nonlinearity but excludes items such as chart paper accuracy or electrical drift (see Dynamic Error Band).

Step-function response. The characteristic curve or output plotted against time resulting from the input application of a step function (a function that is zero for all values of time before a certain instant, and a constant for all values of time thereafter).

Threshold. The smallest stimulus or signal that results in a detectable output.

Time constant. The time required for an exponential quantity to change by an amount equal to 0.632 times the total change required to reach steady state for first-order systems.

Transducer. A device for translating the changing magnitude of one kind of quantity into corresponding changes of another kind of quantity. The second quantity often has dimensions different from the first and serves as the source of a useful signal. The first quantity may be considered an input and the second an output. Significant energy may or may not transfer from the transducer's input to output.

Uncertainty. An estimated value for the error, *i.e.*, what an error might be if it were measured by calibration. Although uncertainty may be the result of both accuracy and precision errors, only precision error can be treated by statistical methods.

Zero shift. Drift in zero indication of an instrument without any change in measured variable.

ERROR ANALYSIS

The measurement of any physical quantity such as length, mass, time, etc. is rarely made without error. The only measurement that has any possibility of being without error is one that involves the counting of discrete items. The objective of a measurement is to determine the value of the specific quantity to be measured (measurand). In general, the result of a measurement is only an estimate of the value of the measurand; thus it is complete only when an uncertainty for that estimate is also given.

The concepts of *error* and *uncertainty* are often confusing, and, in many cases, the two are not clearly distinguished. The error of a measurement is the difference between the measured value of a quantity and its "true value." The uncertainty expresses incomplete knowledge about the effects of errors in measurements. (*Note*: The word uncertainty is used in two senses. It refers to both the general concept and to specific quantitative measures, such as the standard deviation.) The terms error and true value are ideal concepts based on unknowable quantities.

The error in a measurement result is often composed of a number of individual errors from many sources. Error analysis is the study and evaluation of the effects these individual errors have on the total error of a measurement result. The error of a measurement can never be completely known; at best, a range of values within which the true value of a measurand is believed to lie can be determined. This range of values is the uncertainty, an expression of the possible magnitude of the error. In arriving at a realistic measure of uncertainty, the effects of all potential sources of error should be evaluated.

Error Sources

Measurement generally consists of a sequence of operations or steps. Virtually every step introduces a conceivable source of error the effect of which must be assessed. The following list is representative of the most common, but not all, sources of error.

- Inaccuracy in the mathematical model that describes the physical quantity
- Inherent stochastic variability of the measurement process
- Uncertainties in measurement standards and calibrated instrumentation
- Time-dependent instabilities due to gradual changes in standards and instrumentation
- Effects of environmental factors such as temperature, humidity, and pressure
- Values of constants and other parameters obtained from outside sources
- Uncertainties arising from interferences, impurities, inhomogeneity, inadequate resolution, and incomplete discrimination
- Computational uncertainties and data analysis
- Incorrect specifications and procedural errors
- Laboratory practice including handling techniques, cleanliness, and operator techniques, etc.

Error Classifications

Measurement includes two properties: (1) repeated measurements of the same quantity will disagree, and (2) the limiting mean might differ from the *true value* of the quantity of interest. (The limiting mean μ is the value the sample average converges to as the number of measurements are increased indefinitely. If $\bar{x}_n$ is the sample average based on n measurements, as $n \to \infty$, $\bar{x}_n \to \mu$.) These properties are the result of two kinds of errors—*random* and *systematic*. This classification of error is based on the way it behaves under repeated measurements of the same quantity under nearly identical measurement conditions.

Random errors are associated with effects that produce variations in repeated observations of the measurand. The variations are assumed to arise from the inability to hold completely constant all the variables and factors that can affect the measurement. Each measurement is a single realization of a hypothetical infinite population of similar measurements, and for that measurement, the random error is not known in sign or magnitude. The random error cannot be corrected for. Its effect can be reduced by increasing the number of measurements. What is known about the error is expressed as a limit based on statistical confidence intervals.

An error that remains unchanged when the measurement is repeated under substantially the same conditions is termed a *systematic error.* They cause all measurements to be in error by the same amount and, as such, cannot be detected by replicate measurements. For example, any error in a calibrated instrument will affect all measurements by the same amount. Some systematic errors may be estimated and compensated for by applying appropriate corrections. However, since systematic error cannot be known completely, some uncertainty is associated with the correction. Knowledge concerning systematic error is expressed by bounds that cover the error.

A graphical depiction of random and systematic errors is given in Figure 1. The (total) error in a measurement is simply the difference between the measured value x_i and the true value τ. This error is given by

$$\epsilon_i = x_i - \tau \tag{1}$$

The curve is the *normal* or *Guassian* distribution and is the theoretical distribution function for the conceptual infinite population of measurements that generated x_i. This distribution is characterized by a limiting mean μ and standard deviation σ. The random error associated with taking x_i as a measure of μ is given by

$$\epsilon_i = x_i - \mu \tag{2}$$

while the systematic error is given by

$$\delta = \mu - \tau \tag{3}$$

The total error ϵ_i is composed of two components, or

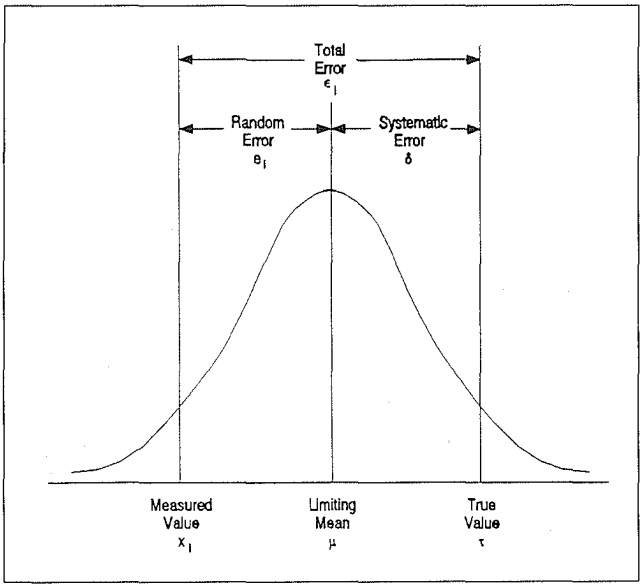

Fig. 1 Graphical Depiction of Error Components

$$\epsilon_i = x_i - \tau$$
$$= (x_i - \mu) + (\mu - \tau)$$
$$= \text{Random} + \text{Systematic} \quad (4)$$

Another measurement, *e.g.*, x_j, will give a different value as an estimate for τ. The systematic error will remain the same, but the random error $(x_j - \mu)$ will, in general, be different.

Assessment of Random Errors

The magnitude of a specific random error cannot be established because it is a chance event from a distribution of possible outcomes. The distribution is characterized by a standard deviation σ, which describes the spread of possible values. This standard deviation is estimated from repeated measurements, $x_1, x_2, \cdots, x_n$ and is given by s, where

$$s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{(n-1)}} \text{ and } \bar{x} = \sum_{i=1}^{n} \frac{x_i}{n} \quad (5)$$

Usually, the mean of a number of measurements $\bar{x}$ is taken as the measurement result. In this case, the effects of random error are reduced, and a measure of the uncertainty in $\bar{x}$ is given by the standard deviation of the mean (or the standard error) and computed by

$$s_{\bar{x}} = s/\sqrt{n} \quad (6)$$

The limit to random error for $\bar{x}$ at the $(1 - \alpha)$ confidence level is

$$t_{\alpha/2}(\nu)\, s_{\bar{x}} \quad (7)$$

where $t_{\alpha/2}(\nu)$ is the upper $\alpha/2$ percentage point of a t-distribution with ν degrees of freedom. Common values for α are 0.05 and 0.01, corresponding to 95 and 99% confidence intervals for μ, respectively. Often, instead of using the t-statistic, the random uncertainty is given by two or three times the standard deviation.

If there are several sources of random error affecting the measured quantity, a total standard deviation is computed; this accounts for the combined effect of the individual sources of error. A discussion of the statistical methods for more complex error models can be found in Croakin (1984), Mandel (1986), Ku (1966), and Eisenhard (1963).

Assessment of Systematic Errors

The evaluation of systematic errors is more troublesome and problematic and generally is not amenable to the use of statistical methods. Contributions to systematic error are from auxiliary quantities, constants, corrections, and so forth. The effects of these errors are often determined by subjective methods and are largely based on a subject matter expertise. Their magnitudes may be based on experimental verification, but judgment and experience on the part of the experimentalist may have to be used.

Since the systematic errors are not reliably known, credible bounds must be estimated. Credible bounds are analogous to limits to random error, in that they should be large enough to guarantee coverage for the systematic error with high reliability. Each systematic uncertainty component is considered a quasi-absolute upper bound for the effect of the error. Its magnitude is typically estimated in terms of an interval from $-\delta$ to $+\delta$. Technical literature should be consulted for specific applications of credible bounds.

Where several sources of systematic error exist, estimated bounds $\pm\delta_i$ are obtained for each component. The question of how to combine these into an overall systematic uncertainty is much debated, and there is generally no agreement on how these various bounds should be combined. The two most common methods of combining the components are by linear addition and quadrature addition (root-sum-square).

Overall Uncertainty

The result of a measurement is only an estimate of the value of the measurand, because of uncertainty due to random error and with corrections for both the known and unknown systematic errors. The uncertainty of a measurement is, therefore, a measure of the extent to which it *may* be in error, *i.e.*, how well it estimates the value of the measurand.

While it is important to identify and place limits on individual error sources, an overall uncertainty that accounts for the combined effect of all the sources of error is often needed. Several procedures combine the individual uncertainty components into an overall uncertainty.

One method is to linearly add all the systematic uncertainty components to the random uncertainty component. Thus, if there are k sources of systematic error, each having bounds given by δ_i, and s is the total standard deviation from all sources of random error, then the overall uncertainty U is given by

$$U = ts + \sum_{i=1}^{k} \delta_i \quad (8)$$

where t is the experimentalist's t-value.

Two other methods have also been used. These add in quadrature the systematic uncertainty components, and either add the resulting quantity linearly to the random uncertainty

$$U = ts + \sqrt{\sum_{i=1}^{k} \delta_i^2} \quad (9)$$

or add in quadrature to the random uncertainty

$$U = \sqrt{(ts)^2 + \sum_{i=1}^{k} \delta_i^2} \quad (10)$$

The procedures in Equations (9) and (10) are recommended in the ANSI/ASME standard on measurement uncertainty (ANSI/ASME 1985). Another guideline for the classical treatment of uncertainties can be found in Eisenhart *et al.* (1983).

TEMPERATURE MEASUREMENT

Instruments for measuring temperatures are listed in Table 1. Temperature sensor output must be related to an accepted temperature scale. This is achieved by manufacturing the instrument according to certain specifications or by calibrating it against a temperature standard. To help users conform to standard temperatures and temperature measurements, the International Committee of Weights and Measures (CIPM) has adopted the International Temperature Scale of 1990 (ITS-90).

The unit of temperature of the ITS-90 is the kelvin (K) and has a size equal to the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

The ITS-90 is maintained in the United States by the National Institute of Standards and Technology (NIST), and any laboratory may obtain calibrations from NIST based on this scale.

Benedict (1984), Considine (1985), Quinn (1990), Schooley (1986), DeWitt and Nutter (1988), and the American Institute of Physics' publication *Temperature: Its Measurement and Control in Science and Industry* (1992) cover temperature measurement in more detail.

Table 1 Temperature Measurement

Measurement Means	Application	Approximate Range, °F	Uncertainty, °F	Limitations
Glass-stem thermometers				
Mercury-glass thermometer	Temperature of gases and liquids by contact	−36/1000	0.05 to 3.6	In gases, accuracy affected by radiation
Organic thermometer	Temperature of gases and liquids by contact	−330/400	0.05 to 3.6	In gases, accuracy affected by radiation
Gas thermometer	Primary standard	−456/1200	Less than 0.02	Requires considerable skill to use
Resistance thermometers				
Platinum-resistance thermometer	Precision; remote readings; temperature of fluids or solids by contact	−430/1800	Less than 0.0002 to 0.2	High cost; accuracy affected by radiation in gases
Rhodium-iron resistance thermometer		−460/−400	0.0002 to 0.2	High cost
Nickel-resistance thermometer	Remote readings; temperature by contact	−420/400	0.02 to 2	Accuracy affected by radiation in gases
Germanium-resistance thermometer	Remote readings; temperature by contact	−460/−400	0.0002 to 0.2	
Thermistors	Remote readings; temperature by contact	Up to 400	0.0002 to 0.2	
Thermocouples				
Pt-Rh/Pt (type S) thermocouple	Standard for thermocouples on IPTS-68, not on ITS-90	32/2650	0.2 to 5	High cost
Au/Pt thermocouple		−60/1800	0.1 to 2	High cost
Types K and N thermocouples	General testing of high temperature; remote rapid readings by direct contact	Up to 2300	0.2 to 18	Less accurate than listed above thermocouples
Iron/constantan (type J) thermocouple		Up to 1400	0.2 to 10	Subject to oxidation
Copper/constantan (type T) thermocouple	Same as above, especially suited for low temperature	Up to 660	0.2 to 5	
Ni-Cr/constantan (type E) thermocouple	Same as above, especially suited for low temperature	Up to 1650	0.2 to 13	
Beckman thermometers (metastatic)	For differential temperature in same applications as in glass-stem thermometer	10 °F scale, used 32–212 °F	0.01	Must be set for temperature to be measured
Bimetallic themometers	For approximate temperature	−4/1200	2, usually much more	Time lag; unsuitable for remote use
Pressure-bulb thermometers				
Gas-filled bulb	Remote-testing	−100/1200	4	Caution must be exercised so that installation is correct
Vapor-filled bulb	Remote-testing	−25/500	4	Caution must be exercised so that installation is correct
Liquid-filled bulb	Remote-testing	−60/2100	4	Caution must be exercised so that installation is correct
Optical pyrometers	For intensity of narrow spectral band of high-temperature radiation (remote)	1500 upward	30	
Radiation pyrometers	For intensity of total high-temperature radiation (remote)	Any range		
Seger cones (fusion pyrometers)	Approximate temperature (within temperature source)	1200/3600	90	
Triple points, freezing/melting and boiling points of materials	Standards	All except extremely high temperatures	Extremely precise	For laboratory use only

Thermometers

Any device that changes monotonically with temperature is a thermometer; however, the term usually signifies an ordinary liquid-in-glass temperature-indicating device. Mercury-filled thermometers have a useful range from −37.8 °F, the freezing point of mercury, to about 1000 °F, near which the glass usually softens. Lower temperatures can be measured with organic-liquid-filled thermometers, *e.g.*, alcohol, with ranges of −330 to 400 °F. During manufacture, thermometers are roughly calibrated for at least two temperatures, often the freezing and boiling points of water; space between the calibration points is divided into desired scale divisions. Thermometers that are intended for precise measurement applications have scales etched into the glass that forms their stems. The probable error for as-manufactured, etched-stem thermometers is ±1 scale division. The highest quality mercury thermometers may have uncertainties of ±0.06 to ±4 °F, if they have been calibrated by comparison against primary reference standards.

Liquid-in-glass thermometers are used for many applications within the HVAC industry. Some of these uses include local indication of process fluids related to HVAC systems, such as cooling and heating fluid temperatures, and air temperatures.

The use of mercury-in-glass thermometers as temperature measurement standards is fairly common because of their relatively high accuracy and low cost. Such thermometers used as references must be calibrated on the ITS-90 by comparison in a uniform bath with a standard platinum resistance thermometer that has been calibrated either by the appropriate standards agency or a laboratory that has direct traceability to the standards agency and the ITS-90. Such a calibration is necessary in order to determine the proper corrections to be applied to the scale readings. For application and calibration of liquid-in-glass thermometers, refer to NIST (1976, 1986).

Liquid-in-glass thermometers are calibrated by the manufacturer for total or partial stem immersion. If a thermometer calibrated for total immersion is used at partial immersion, *i.e.*, with a portion of the liquid column at a temperature different from that of the bath, an emergent stem correction must be made. This correction can be calculated as follows:

$$\text{Stem correction} = K_n (t_b - t_s) \qquad (11)$$

where

K = differential expansion coefficient of mercury or other liquid in glass. K is 0.00016 for Celsius mercurial thermometers. For K values for other liquids and specific glasses, refer to AIP (1962).
n = number of degrees that liquid column emerges from bath
t_b = temperature of bath
t_s = average temperature of emergent liquid column of n degrees

Sources of Thermometer Errors

A thermometer measuring gas temperatures can be affected by radiation from surrounding surfaces. If the temperature is approximately the same as that of the surrounding surfaces, radiation effects can be ignored. If the temperature differs considerably from that of the surroundings, radiation effects should be minimized by *shielding* or *aspiration* (ASME 1985a). Shielding may be provided by highly reflective surfaces placed between the thermometer bulb and the surrounding surfaces, so that air movement around the bulb is not appreciably restricted (Parmelee and Huebscher 1946). Improper shielding can increase errors. Aspiration results from passing a high-velocity stream of air or gas over the thermometer bulb.

When a *thermometer well* within a container or pipe under pressure is required, the thermometer should fit snugly and be surrounded with a high thermal conductivity material (oil, water, or mercury, if suitable). Liquid in a long, thin-walled well is advantageous for rapid response to temperature changes. The surface of the pipe or container around the well should be insulated to eliminate heat transfer to or from the well.

Industrial thermometers are available for permanent installation in pipes or ducts. These instruments are fitted with metal guards to prevent breakage and are useful for many other purposes. The considerable heat capacity and conductance of the guards or shields can cause errors, however.

Ample time for the thermometer to attain temperature equilibrium with the surrounding fluid prevents excessive errors in temperature measurements. When reading a liquid-in-glass thermometer, the eye should be kept at the same level as the top of the liquid column to avoid parallax.

Resistance Thermometers

Resistance thermometers depend on a change of the electrical resistance of a sensing element (usually metal) with a change in temperature; resistance increases with increasing temperature. The use of resistance thermometers largely parallels that of thermocouples, although readings are usually unstable above about 1000 °F. Two-lead temperature elements are not recommended, since they do not permit correction for lead resistance. Three leads to each resistor are necessary to obtain consistent readings, and four leads are preferred. Wheatstone bridge circuits or 6-1/2-digit multimeters can be used for measurements.

A typical circuit used by several manufacturers is shown in Figure 2. In this design, a differential galvanometer is used, in which coils L and H exert opposing forces on the indicating needle. Coil L is in series with the thermometer resistance AB, and coil H is in series with the constant resistance R. As the temperature falls, the resistance of AB decreases, allowing more current to flow through coil L than coil H. This causes an increase in the force exerted by coil L, pulling the needle down to a lower reading. Likewise, as the temperature rises, the resistance of AB increases, causing less current to flow through coil L than coil H. This forces the indicating needle to a higher reading. Rheostat S must be adjusted occasionally to maintain a constant flow of current.

The resistance thermometer is more costly to make and more likely to have considerably longer response times than thermocouples. A resistance thermometer gives best results when used to measure steady or slowly changing temperature.

Resistance Temperature Devices

Resistance temperature devices or RTDs are typically constructed from platinum, rhodium-iron, nickel, nickel-iron, tungsten, or copper. These devices are further characterized by their simple circuit designs, a high degree of linearity, good sensitivity,

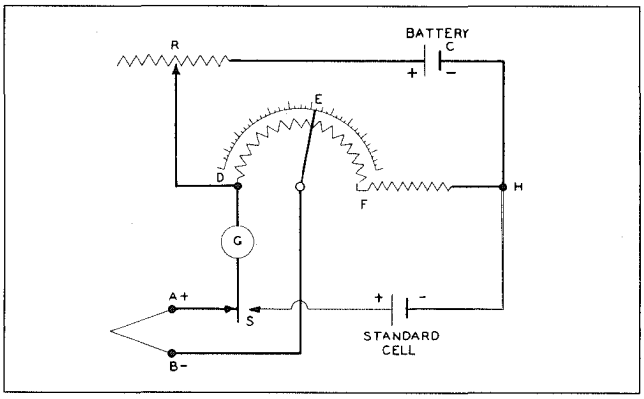

Fig. 2 Basic Thermocouple and Potentiometer Circuit

and excellent stability. The choice of materials for an RTD usually depends on the intended application, where temperature range, corrosion protection, mechanical stability, and cost are some of the selection criteria.

Platinum RTDs. Presently, for HVAC applications, RTDs constructed of platinum are the most widely used. Platinum is extremely stable and corrosion resistant. Platinum RTDs possess high malleability, and can thus be drawn into fine wires. They have a high melting point and can be refined to a high degree of purity, thus attaining highly reproducible properties. Due to these properties, platinum RTDs are used to define the ITS-90 for the range of 13.8033 K (triple point of equilibrium hydrogen) to 1234.93 K (freezing-point temperature of silver).

Platinum resistance temperature devices (PRTs) can measure the widest range of temperatures and are the most accurate and stable temperature sensors. Their resistance-temperature relationship is one of the most linear. The higher the purity of platinum, the more stable and accurate the sensor. With high-purity platinum, primary grade PRTs are capable of achieving reproducibilities of ±0.00002°F, whereas the minimum uncertainty of a recently calibrated thermocouple is only ±0.4°F.

Platinum RTD design. The most widely used RTD is designed with a resistance of 100 Ω at 32°F (R_0 = 100 Ω). Other resistance values are available where lower resistances are used at temperatures above 1100°F. The lower the resistance value, the faster the response time for sensors of the same size.

Thin-film 1000 Ω and higher platinum RTDs are readily available. They have the excellent linear properties of lower resistance platinum RTDs and are more cost-effective since they are mass produced and have lower platinum purity. However, the problem with many platinum RTDs with R_0 values of greater than 100 Ω is the difficulty in obtaining transmitters or electronic interface boards from sources other than the platinum RTD manufacturer. In addition to a *nonstandard* interface, higher R_0 value platinum RTDs may have higher self-heating losses if the excitation current is not controlled properly.

Thin-film RTDs have the advantages of lower cost and smaller sensor size. They are specifically adapted to surface mounting. Thin-film sensors tend to have an accuracy limitation of ±0.1% or 0.2°F. This may prove to be adequate for most HVAC applications; only in tightly controlled facilities may users wish to install the standard wire-wound platinum RTDs with accuracies of ±0.01% or 0.02°F (these are available upon special request for certain temperature ranges).

Regardless of the R_0 resistance value of RTDs, their assembly and construction are relatively simple. The electrical connections come in three basic types, depending on the number of wires to be connected to the resistance measurement circuitry. Either two, three, or four wires are used for electrical connection using a Wheatstone bridge or a variation of it (Figure 3). In the basic two-wire configuration, the resistance of the RTD is measured through the two connecting wires. Since the connecting wires extend from the site of the temperature measurement, any additional changes in resistivity due to a different temperature may change the measured resistance.

Three- and four-wire assemblies are built to compensate for the connecting lead resistance values. The original three-wire circuit improved the resistance measurement by adding a compensating wire to the voltage side of the circuit. This helps reduce self-heating and part of the connecting wire resistance. When more accurate measurements are required, better than ±0.2°F, the four-wire bridge is recommended. The four-wire bridge eliminates all connecting wire resistance errors.

All the bridges discussed here are dc circuits and were used extensively until the advent of precision ac circuits using microprocessor-controlled ratio transformers, dedicated analog-to-digital convertors, and other solid-state devices that measure resistance with uncertainties of less than 1 ppm. The newer resistance measurement devices allow for more portable thermometers, lower cost, ease of use, and the application of high-precision temperature measurement in industrial uses.

Thermistors

Certain semiconductor compounds (usually sintered metallic oxides) exhibit large changes in resistance with temperature, usually decreasing as the temperature increases. For use, the thermistor element may be connected by lead wires into a galvanometer bridge circuit and calibrated. A 6-1/2-digit multimeter and a constant-current source, with a means for reversing the current to eliminate thermal electromotive force (emf) effects, may also be used. This method of measurement is easier, faster, and may be more precise and accurate. Thermistors are usually applied to electronic temperature compensation circuits, such as thermocouple reference junction compensation, or to other applications where high resolution and limited operating temperature ranges exist. Figure 4 illustrates a typical thermistor circuit.

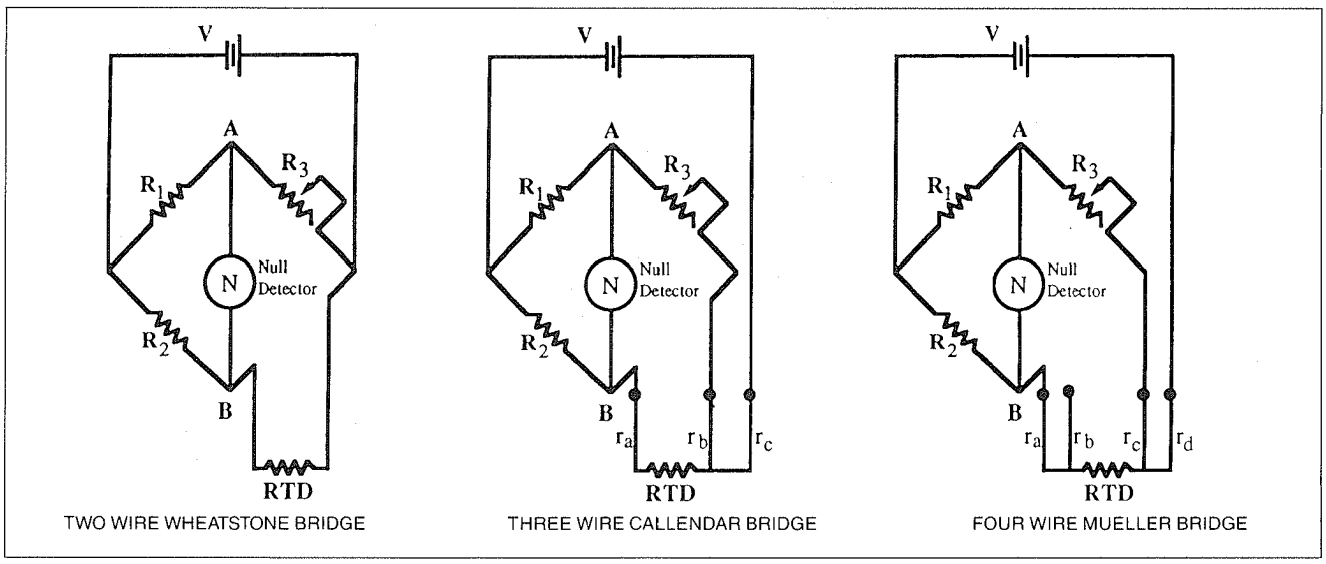

Fig. 3 Typical Resistance Temperature Bridge Circuits

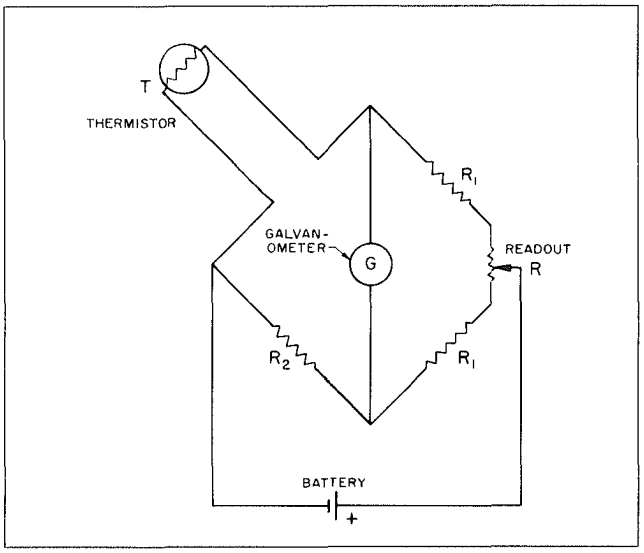

Fig. 4 Basic Thermistor Circuit

Thermocouples

When two wires of dissimilar metals are joined by soldering, welding, or twisting, they form a thermocouple junction or thermojunction. An emf that depends on the wire materials and the junction temperature exists between the wires.

Thermocouples for temperature measurement yield less precise results than those for platinum resistance thermometers; but, except for glass thermometers, thermocouples are the most common instruments of temperature measurement for the range of 32 to 1800 °F. Due to their low cost, moderate reliability, and ease of use, thermocouples continue to maintain widespread acceptance.

The most commonly used thermocouples in industrial applications are assigned letter designations. The tolerances of such commercially available thermocouples are given in Table 2.

Because the measured emf is a function of the *difference* in temperature and the type of dissimilar metals used, a known temperature at one junction is required, whereas the remaining junction temperature may be calculated. Common practice refers to the *reference* junction as the one with a known temperature and the *measured* junction as the unknown temperature junction. The reference junction is typically kept at a reproducible temperature, such as the ice point of water.

Various systems are used to maintain the reference junction temperature—a mixture of ice and water contained in an insulated flask, or commercially available thermoelectric coolers to maintain the ice point temperature automatically within a reference chamber. When these systems cannot be used in an application, measuring instruments with automatic reference junction temperature compensation may be used.

As previously described, the principle for measuring temperature with a thermocouple is based on the accurate measurement of the Seebeck voltage. The acceptable dc voltage measurements methods are (1) millivoltmeter, (2) millivolt potentiometer, and (3) a high-input impedance digital voltmeter. Many digital voltmeters include built-in software routines for the direct calculation and display of temperature. Regardless of the method selected, many options to simplify the measurement process are available.

Solid-state digital readout devices in combination with a millivolt or microvoltmeter, as well as packaged thermocouple readouts with built-in cold junction and linearization circuits, are available. The latter requires a proper thermocouple to provide direct meter reading of temperature. Accuracies approaching or surpassing that of potentiometers can be attained, depending on the instrument quality. This method is popular because it eliminates the null balancing requirement and reads temperature directly in a digital readout.

Thermocouple wire is selected by considering the temperature to be measured, the corrosion protection afforded the thermocouple, and the precision and service life required. Type T thermocouples are suitable for temperatures up to 220 °F; type J, up to 1400 °F; and types K and N, up to 2300 °F. Higher temperatures require noble metal thermocouples (types S, R, or B), which have

Table 2 Tolerances on Initial Values of Electromotive Force versus Temperature

Thermocouple Type	Material Identification	Temperature Range, °F	Reference Junction Tolerance, 32 °F	
			Standard Tolerance (whichever is greater)	Special Tolerance (whichever is greater)
T	Copper versus Constantan	32 to 700	±1.8° or ±0.75%	±0.9 °F or ±0.4%
J	Iron versus Constantan	32 to 1400	±4 °F or ±0.75%	±2 °F to ±0.4%
E	Nickel-10% Chromium versus Constantan	32 to 1600	±3.1 °F or ±0.5%	±1.8 °F or ±0.4%
K	Nickel-10% Chromium versus 5% Aluminum, Silicon	32 to 2300	±4 °F or ±0.75%	±2 °F or ±0.4%
N	Nickel-14% Chromium, 1.5% Silicon versus Nickel-4.5% Silicon, 0.1% Magnesium	32 to 2300	±4 °F or ±0.75%	±2 °F or ±0.4%
R	Platinum-13% Rhodium versus Platinum	32 to 2700	±2.7 °F or ±0.25%	±1.1 °F or ±0.1%
S	Platinum-10% Rhodium versus Platinum	32 to 2700	±2.7 °F or ±0.25%	±1.1 °F or ±0.1%
B	Platinum-30% Rhodium versus Platinum-6% Rhodium	1600 to 3100	±0.5%	±0.25%
T[a]	Copper versus Constantan	−328 to 32	±1.8 °F or ±1.5%	b
E[a]	Nickel-10% Chromium versus Constantan	−328 to 32	±3.1 °F or ±1%	b
K[a]	Nickel-10% Chromium versus 5% Aluminum, Silicon	−328 to 32	±4 °F or ±2%	b

Source: ASTM E230-87, Temperature-Electromotive Force (EMF) Tables For Standardized Thermocouples.

Notes:

Tolerances in this table apply to new thermocouple wire, normally in the size range of 0.01 to 0.1 in. diameter and used at temperatures not exceeding the recommended limits.

[a]Thermocouples and thermocouple materials are normally supplied to meet the tolerance specified in the table for temperatures above 32 °F. The same materials, however, may not fall within the tolerances given in the second section of the table when operated below freezing (32 °F). If materials are required to meet tolerances at low temperatures, the purchase order must state so. Selection of material usually will be required.

[b]Little information is available to justify establishing special tolerances for below-freezing temperatures. Limitied experience suggests the following special tolerances for types E and T thermocouples:

Type E −330 to 32 °F; ±2 °F or ±0.5% (whichever is greater)
Type T −330 to 32 °F; ±1 °F or ±0.8% (whichever is greater)

These tolerances are given only as a guide for discussion between purchaser and supplier.

a higher initial cost and do not develop as high an emf as the base metal thermocouples. Thermocouple wires of the same type have small compositional variation from lot to lot from the same manufacturer and especially from different manufacturers. Consequently, calibrating samples from each wire spool is essential for precision. Calibration data on wire may be obtained from the manufacturer.

Reference functions are available for relating temperature and emf of letter-designated thermocouple types. Such functions are easy to use with computers. The functions depend on thermocouple type and on the range of temperature; they are used to generate reference tables of emf as a function of temperature but are not well suited for calculating temperatures directly from values of emf. Approximate inverse functions are available, however, for calculating temperature and are of the form

$$t_{90} = \sum_{i=0}^{n} a_i E^i \tag{12}$$

where t_{90} = temperature, and E = voltage. Burns *et al.* (1992) give the reference functions and approximate inverses for all letter-designated thermocouples.

The emf of a thermocouple, as measured with a high-input impedance device, is independent of the diameters of its constituent wires. Thermocouples with small-diameter wires respond faster to temperature changes and are less affected by radiation than larger ones. Large-diameter wire thermocouples, however, are necessary for high-temperature work when wire corrosion is a problem. For use in heated air or gases, thermocouples are often shielded and sometimes aspirated. An arrangement for avoiding error because of radiation involves using several thermocouples of different wire sizes and estimating the true temperature by extrapolating readings to zero diameter.

By using thermocouples, temperatures can be indicated or recorded remotely on conveniently located instruments. Since thermocouples can be made of small-diameter wire, they can be used to measure temperatures within thin materials, within narrow spaces, or in otherwise inaccessible locations.

Thermocouples in series, with alternate junctions maintained at a common temperature, produce an emf that, when divided by the number of thermocouples, gives the average emf corresponding to the temperature difference between two sets of junctions. This series arrangement of thermocouples, often called a thermopile, is used to increase the sensitivity and is often used for measuring small temperature changes and differences.

A number of thermocouples of the same type, connected in parallel and having a common reference junction, is useful to obtain an average temperature of an object or volume. In such measurements, however, it is important that the electrical resistances of the individual thermocouples be the same. The use of thermocouples in series and parallel arrangements is discussed in ASTM STP 470B (1981).

The thermocouple is useful in determining surface temperature. It can be attached to a metal surface in several ways. For permanent installations, soldering, brazing, or peening is suggested. For the latter, a small hole is drilled and the thermocouple measuring junction is driven into it. For temporary arrangements, thermocouples can be attached by tape, adhesive, or putty-like material. For boiler or furnace surfaces, furnace cement should be used. To minimize the possibility of error caused by heat conduction along wires, a surface thermocouple should be made of fine wires placed in close contact with the surface being measured for about an inch from the junction to ensure good thermal contact. The wires must be insulated electrically from each other and from the metal surface (except at the junction).

Thermocouple construction. The thermocouple wires are typically insulated with fibrous glass, fluorocarbon resin, or ceramic insulators. Another form of thermocouple consists of the thermocouple wires being insulated with compacted ceramic insulation inside a metal sheath. This form of thermocouple provides both mechanical protection and protection from stray electromagnetic fields. The measuring junction may be exposed or enclosed within the metal sheath. The enclosed junction may be either grounded or ungrounded to the metal sheath.

For the exposed junction type, the measuring junction is in direct contact with the process stream; thus, it is subject to corrosion or contamination but provides a fast temperature response. The enclosed junction type, in which the thermocouple wires are welded to the metal sheath, provides for electrical grounding, as well as for mechanical and corrosion protection. This type, however, has a slower response time than the exposed junction type. With the ungrounded enclosed junction construction, the response time is even slower, but the thermocouple wires are isolated electrically and are less susceptible to some forms of mechanical strain than those of the grounded construction.

Semiconductor devices. In addition to the positive resistance coefficient RTDs and the negative resistance coefficient thermistor, there are two other types of devices that vary resistance or impedance with temperature. While the principle of their operation has long been known, their reliability was questioned because of imprecise manufacturing techniques. Improvements in silicon microelectronics manufacturing techniques during the 1980s have improved to the point where low-cost, precise temperature sensors are now commercially available.

Elemental semiconductors. Through the use of controlled doping of impurities into elemental germanium, a germanium semiconductor is a reliable temperature sensor for cryogenic temperature measurement in the range from 1.8 to 150 R.

Junction semiconductors. The first simple junction semiconductor device consisted of a single diode or transistor, in which the forward-connected base emitter voltage is very sensitive to temperature. Today the more common form is a pair of diode-connected transistors, which make the device suitable for ambient temperature measurement. Applications include thermocouple reference junction compensation.

The primary advantage of silicon transistor temperature sensors are their extreme linearity and exact R_0 value. Another advantage is the ability to incorporate signal conditioning circuitry into the same device as the sensor element. As with thermocouples, these semiconductors require highly precise manufacturing techniques, extremely precise voltage measurements, multiple point calibration, and temperature compensation to achieve an accuracy as high as ±0.02 °F, but with a much higher cost. Lower cost devices will achieve accuracies of ±0.2 °F, using mass manufacturing techniques and single point calibration. A mass-produced silicon temperature sensor can be easily interchanged. If one device fails, only the sensor element need be changed. Electronic circuitry can be used to recalibrate the new device.

Winding temperature. The winding temperature of electrical operating equipment is usually determined from the resistance change of these windings in operation. With copper windings, the relation between these parameters is

$$(R_1/R_2) = (148.1 + t_1)/(148.1 + t_2) \tag{13}$$

where

R_1 = winding resistance at temperature t_1, °F
R_2 = winding resistance at temperature t_2, °F

The classical method of determining winding temperature is to measure the equipment inoperative and temperature-stabilized at room temperature. After the equipment has operated sufficiently

to cause temperature stabilization under load conditions, the winding resistance should be measured again. The latter value is obtained by taking resistance measurements at known short time intervals after shutdown. These values may be extrapolated to zero time to indicate the winding resistance at the time of shutdown. The obvious disadvantage of this method is that the device must be shut down to determine winding temperature. A circuit described by Seely (1955), however, makes it possible to measure resistances while the device is operating.

Sampling and Averaging

Although temperature is usually measured within, and is associated with, a relatively small volume (depending on the size of the thermometer), it can also be associated with an area such as on a surface or in a flowing stream. To determine average stream temperature, the cross section must be divided into smaller areas and the temperature of each area measured. The temperatures measured are then combined into a weighted mass flow average either by (1) using equal areas and multiplying each temperature by the fraction of total mass flow in its area, or (2) using areas of size inversely proportional to mass flow and taking a simple arithmetic average of the temperatures in each. A means of mixing or selective sampling may be preferable to these cumbersome procedures. While mixing can occur from turbulence alone, transposition is much more effective. In transposition, the stream is divided into parts determined by the type of stratification, and alternate parts pass through one another.

Static Temperature versus Total Temperature

When a fluid stream impinges on a temperature-sensing element such as a thermometer or thermocouple, the element is at a temperature greater than the true stream temperature. The difference is a fraction of the temperature equivalent of the stream velocity t_e.

$$t_e = V^2/(2c_p) \tag{14}$$

where

t_e = temperature equivalent of stream velocity, °F
V = velocity of stream, fpm
c_p = specific heat at constant pressure, Btu/lb · °F

This fraction of the temperature equivalent of the velocity is the *recovery factor*, and it varies from 0.6 to 0.8 °F (for bare thermometers) to 1.0 °F (for aerodynamically shielded thermocouples). For precise temperature measurement, each temperature sensor must be calibrated to determine its recovery factor. However, for most applications where air velocities are below 2000 fpm, this factor can be omitted.

Various temperature sensors are available for temperature measurement in fluid streams. The principal sensors are the *static temperature thermometer*, which indicates true stream temperature but is cumbersome, and the *thermistor*, used for accurate temperature measurement within a limited range.

Infrared Radiometers

Infrared radiation thermometers, also known as remote temperature sensors (Hudson 1969), permit noncontact measurement of surface temperature over a wide range. In these instruments, radiant flux from the observed object is focused by an optical system onto an infrared detector that generates an output signal, proportional to the incident radiation, which can be read from a meter or display unit. Point and scanning radiometers are available; the latter are able to display the temperature variation existing within the field of view.

Radiometers are usually classified according to the detector used—either thermal or photon. In thermal detectors, a change in electrical property is caused by the heating effect of the incident radiation. Examples of thermal detectors are the thermocouple, thermopile, and metallic and semiconductor bolometers. In photon detectors, a change in electrical property is caused by the surface absorption of incident photons. Because these detectors do not require an increase in temperature for activation, their response time is much shorter than that of thermal detectors. Scanning radiometers usually use photon detectors.

A radiometer only measures the power level of the radiation incident on the detector; this incident radiation is a combination of the thermal radiation emitted by the object and the surrounding background radiation reflected from the surface of the object. An accurate measurement of the temperature, therefore, requires knowledge of the long-wavelength emissivity of the object as well as the effective temperature of the thermal radiation field surrounding the object. Calibration against an internal or external source of known temperature and emissivity is required in order to obtain true surface temperature from the radiation measurements.

The temperature resolution of a radiometer decreases as the object temperature decreases. For example, a radiometer that can resolve a temperature difference of 0.5 °F on an object near 70 °F may only resolve a difference of 2 °F on an object at 32 °F.

Infrared Thermography

Infrared thermography is the discipline concerned with the acquisition and analysis of thermal information in the form of images from an infrared imaging system. An infrared imaging system consists of (1) an infrared television camera and (2) a display unit. The infrared television camera scans a surface and senses the self-emitted and reflected radiation viewed from the surface. The display unit contains either a cathode-ray tube (CRT) that displays a gray-tone or color-coded thermal image of the surface or a color LCD screen. A photograph of the image on the CRT is called a thermogram. An introductory treatise on infrared thermography is given by Paljak and Pettersson (1972).

Thermography has been used successfully to detect missing insulation and air infiltration paths in building envelopes (Burch and Hunt 1978). Standard practices for conducting thermographic inspections of buildings are given in ASTM (1989a). A technique to quantitatively map the heat loss in building envelopes is given by Mack (1986).

Aerial infrared thermography of buildings is effective in identifying regions of an individual built-up roof that have wet insulation (Tobiasson and Korhonen 1985), but it is ineffective in ranking a group of roofs according to their thermal resistance (Goldstein 1978, Burch 1980). In this latter application, the emittances of the separate roofs and outdoor climate (*i.e.*, temperature and wind speed) throughout the microclimate often produce changes in the thermal image that may be incorrectly attributed to differences in thermal resistance.

Industrial applications include locating defective or missing pipe insulation in buried heat distribution systems, surveys of manufacturing plants to quantify energy loss from equipment, and locating defects in coatings (Bentz and Martin 1987).

PRESSURE MEASUREMENTS

Definitions

Pressure is the force exerted per unit area by a pressure media, generally a liquid or gas. Pressure so defined is also sometimes referred to as **absolute pressure**. Thermodynamic and material properties are expressed in terms of absolute pressures; thus, the properties of a refrigerant will be given in terms of absolute pressures. **Vacuum** refers to low pressures, less than atmospheric.

Differential pressure is the difference between two absolute pressures. In many cases, the differential pressure can be very small compared to either of the absolute pressures (these are often referred to as low-range, high-line differential pressures). A common example of differential pressures is the pressure drop, or difference between inlet and outlet pressures, across a filter or flow element.

Gage pressure is a special case of differential pressure where one of the pressures (reference pressures) is atmospheric pressure. Many pressure gages, including most refrigeration test sets, are designed to make gage pressure measurements, and there are probably more gage pressure measurements made than any other. Gage pressure measurements are often used as surrogates for absolute pressures. However, because of variations in atmospheric pressure, due to elevation (atmospheric pressure in Denver, CO is about 81% of sea-level pressure) and weather changes, the measurement of gage pressures to determine absolute pressures can significantly restrict the accuracy of the measured pressure, unless corrections are made for the local atmospheric pressure at the time of the measurement.

Pressures can be further classified as **static** or **dynamic**. Static pressures have a small or undetectable change with time; dynamic pressures include a significant pulsed, oscillatory, or other time-dependent component. Static pressure measurements are the most common, but equipment such as blowers and compressors can generate significant oscillatory pressures at discrete frequencies. Flow in pipes and ducts can generate resonant pressure changes, as well as turbulent "noise" that can span a wide range of frequencies.

Units

A plethora of pressure units, many of them poorly defined, are in common use. The internationally accepted pressure unit (SI unit) is the newton/square meter, called the pascal (Pa). The bar is an acceptable alternate unit, but it should not be introduced where it is not used at present. Although not internationally recognized, the pound/square inch (psi) is a widely used and properly defined unit. Also widely used, but not as rigorously defined and, therefore, a potential source of error, are units based on the length of liquid columns, including inches of mercury (in. Hg), mm of mercury (mm Hg), and inches of water (in. H_2O). The latter is often used for low-range differential pressure measurements. In the case of pounds per square inch, the type of pressure measurement is often indicated by a modification of the unit, *i.e.*, both psi and psia are used to indicate absolute pressure measurements, psid indicates a differential measurement, and psig indicates a gage measurement. No such standard convention exists for other units, and unless explicitly stated, reported values are assumed to be absolute pressures. Conversion units for different pressure units can be found in Chapter 35.

The differences between the conversion factors for inches of mercury and inches of water at the different temperatures is indicative of the errors that can arise from uncertainties as to how these units are defined.

Types of Pressure-Measuring Instruments

Broadly speaking, pressure instruments can be divided into three different categories—standards, mechanical gages, and electromechanical transducers. Standards instruments are used for most-accurate calibrations. The most common, and potentially the most accurate standard, the liquid-column manometer, is used for a variety of applications, including field applications. Mechanical pressure gages are generally the least expensive and the most common pressure instruments. However, electromechanical transducers have become much less expensive and are easier to use, so that they are being used more often.

Pressure Standards

Liquid-column manometers measure pressure by determining the vertical displacement of a liquid of known density in a known gravitational field. Typically they are constructed as a "U" tube of transparent material (glass or plastic). The pressure to be measured is applied to one side of the U tube. If the other (reference) side is evacuated (zero pressure), the manometer measures absolute pressure, and if the reference side is open to the atmosphere, it measures gage pressures; if the reference side is connected to some other pressure, the manometer measures the differential between the two pressures. Manometers filled with water and different oils are often used to measure low-range differential pressures. In some low-range instruments, one tube of the manometer is inclined to enhance the readability. Mercury-filled manometers are used for higher range differential and absolute pressure measurements. In the latter case, the reference side is evacuated, generally with a mechanical vacuum pump. Typical full-scale ranges for manometers vary from 10 in. of water to 3 atm.

For pressures above the range of manometers, standards are generally of the piston-gage, pressure-balance, or deadweight-tester type. These instruments apply pressure to the bottom of a vertical piston, which is surrounded by a close-fitting cylinder (typical clearances are millionths of an inch). The pressure generates a force approximately equal to the pressure times the area of the piston. This force is balanced by weights stacked on the top of the piston. If the mass of the weights, the local acceleration of gravity, and the area of the piston (or more properly, the "effective area" of the piston and cylinder assembly) are known, the applied pressure can be calculated. Piston gages generally generate gage pressures with respect to the atmospheric pressure above the piston. They can be used to measure absolute pressures by separately measuring the atmospheric pressure and adding it to the gage pressure determined by the piston gage, or directly by surrounding the top of the piston and weights with an evacuated bell jar. Piston gage full-scale ranges vary from 5 psi to 200,000 psi.

At the other extreme, very low absolute pressures (below about 0.4 in. of water), a number of different types of standards are used. These tend to be specialized and expensive instruments found only in major standards laboratories. However, one low-pressure standard, the McLeod gage, has been used for field applications. Unfortunately, although the theory of the McLeod gage is simple and straightforward, it is difficult to make accurate measurements with this instrument, and major errors can occur when it is used to measure gases that condense or are adsorbed (*e.g.*, water). In general, gages other than the McLeod gage should be used for most low-pressure or vacuum applications.

Mechanical Pressure Gages

Mechanical pressure gages couple a pressure sensor to a mechanical readout, typically a pointer and dial. The most common type employs a Bourdon tube sensor, which is essentially a coiled metal tube of circular or elliptical cross section. Pressure applied to the inside of the tube causes it to uncoil with increasing pressure. A mechanical linkage translates the motion of the end of the tube to the rotation of a pointer. In most cases, the Bourdon tube is surrounded by atmospheric pressure so that the gages measure gage pressure. A few instruments surround the Bourdon tube with a sealed enclosure that can be evacuated for absolute measurements or connected to another pressure for differential measurements. Available instruments vary widely in cost, size, pressure range, and accuracy. Full-scale ranges can vary from 5 to 100,000 psi. Accuracy of properly calibrated and used instruments can vary from 0.1 to 10% of full scale. Generally there is a strong correlation between size, price, and accuracy; larger instruments are more accurate and expensive.

To achieve better sensitivity, some low-range mechanical gages, sometimes called aneroid gages, employ corrugated diaphragms or capsules as sensors. The capsule is basically a short bellows sealed with end caps. These sensors are more compliant than a Bourdon tube and a given applied pressure will cause a larger deflection of the sensor. The inside of a capsule can be evacuated and sealed in order to measure absolute pressures, or connected to an external fitting to allow differential pressures to be measured. Typically, these gages are used for low-range measurements of 1 atm or less. In instruments of better quality, accuracies of 0.1% of reading or better can be achieved.

Electromechanical Transducers

Mechanical pressure gages are generally limited by inelastic behavior of the sensing element, friction in the readout mechanism, and limited resolution of the pointer and dial. These effects can be eliminated or reduced by using electronic techniques to sense the distortion or stress of a mechanical sensing element and electronically convert that stress or distortion to a pressure reading. A wide variety of sensors is used, including Bourdon tubes, capsules, diaphragms, and different resonant structures whose vibration frequency varies with the applied pressure. Capacitive, inductive, and optical lever sensors are used to measure the displacement of the sensor element. In some cases, feedback techniques may be used to constrain the sensor in a null position, minimizing distortion and hysteresis of the sensing element. Temperature control or compensation is often included. Readout may be in the form of a digital display, analog voltage or current, or a digital code. Size varies, but in the case of transducers employing a diaphragm fabricated as part of a silicon chip, the sensor and signal conditioning electronics can be contained in a small transistor package, and the largest part of the device is the pressure fitting. The best of these instruments achieve long-term instabilities of 0.01% of full scale or better, and corresponding accuracies when properly calibrated. Performance of the less expensive instruments can be more on the order of several percent.

While the dynamic response of most mechanical gages is limited by the sensor and readout, the response of some electromechanical transducers can be much faster, allowing measurements of dynamic pressures at frequencies up to 1 kHz and beyond in the case of transducers specifically designed for dynamic measurements. Manufacturers' literature should be consulted as a guide to the dynamic response of specific instruments.

As the measured pressure is reduced below about 1.5 psi, it becomes increasingly difficult to mechanically sense the lower pressures. A variety of gages have been developed that measure some other property of the gas that is related to the pressure. In particular, thermal conductivity gages, known as thermocouple, thermistor, pirani, and convection gages, are used for pressures down to about 0.0004 in. of water. These gages have a sensor tube with a small heated element and a temperature sensor; the temperature of the heated element is determined by the thermal conductivity of the gas, and the output of the temperature sensor is displayed on an analog or digital electrical meter contained in an attached electronics unit. The accuracy of these gages is limited by their nonlinearity, dependence on gas species, and tendency to read high when contaminated. Oil contamination is a particular problem. However, these gages are small, reasonably rugged, and relatively inexpensive; in the hands of a typical user, they will give far more reliable results than a McLeod gage. They can be used to check the base pressure in a system that is being evacuated prior to being filled with refrigerant. They should be periodically checked for contamination by comparing the reading with that from a new, clean sensor tube.

General Considerations

Accurate values of atmospheric or barometric pressure are required for weather prediction and aircraft altimetry. In the United States, a network of calibrated instruments, generally accurate to within 0.1% of reading and located at airports, are maintained by the National Weather Service, the Federal Aviation Administration, and local airport operating authorities. These agencies are generally cooperative in providing current values of atmospheric pressure that can be used to check the calibration of absolute pressure gages or to correct gage pressure readings to absolute pressures. However, the pressure readings generally reported for weather and altimetry purposes are not the true atmospheric pressure, but rather a value adjusted to an equivalent sea level pressure. Therefore, unless located near sea level, it is important to ask for the station or true atmospheric pressure and not to use the values broadcast by radio stations as they are always adjusted values. Further, the atmospheric pressure decreases with increasing elevation at a rate (near sea level) of about 0.001 in. Hg/ft, and corresponding corrections should be made to account for the difference in elevation between the instruments being compared.

As noted before, gage-pressure instruments are sometimes used to measure absolute pressures, and the accuracy of these measurements can be compromised by uncertainties in the atmospheric pressure. This error can be particularly serious when gage-pressure instruments are used to measure a vacuum (negative gage pressures). For all but the most crude measurements, absolute-pressure gages should be used for vacuum measurements; for pressures below about 0.4 in. of water, a thermal conductivity gage should be used.

All pressure gages are susceptible to temperature errors. Several techniques are used to minimize these errors—sensor materials are generally chosen to minimize temperature effects, mechanical readouts can include temperature compensation elements, electromechanical transducers may include a temperature sensor and compensation circuit, and some transducers are operated at a controlled temperature. Clearly, temperature effects are of greater concern for field applications, and it is prudent to check the manufacturers' literature for the temperature range over which the specified accuracy can be maintained. Abrupt temperature changes can also cause large transient errors that may take some time to decay.

The readings of some electromechanical transducers with a resonant or vibrating sensor can depend on the gas species. Although some of these units can achieve calibrated accuracies of the order of 0.01% of reading, they are typically calibrated with dry air or nitrogen, and the readings for other gases can be in error by several percent, quite possibly much more for refrigerants and other high-density gases. High accuracy readings can be maintained by calibrating these devices with the gas to be measured. Manufacturer's literature should be consulted.

The measurement of dynamic pressures is limited not just by the frequency response of the pressure gage, but also by the hydraulic or pneumatic time constant of the connection between the gage and the system to be monitored. As a general rule, the longer the connecting lines and the smaller their diameter, the lower the frequency response of the system. Further, even if only the static component of the pressure is of interest and a gage with a low frequency response is used, a significant pulsating or oscillating pressure component can cause significant errors in pressure gage readings and, in some cases, can damage the gage, particularly gages with a mechanical readout mechanism. In these cases, a filter or snubber should be used to reduce the higher frequency components.

VELOCITY MEASUREMENT

Heating and air-conditioning engineers measure the flow of air more often than any other gases, and the air is usually measured at or near atmospheric pressure. Under this condition, the air can be treated as an incompressible fluid, and simple formulas give

Table 3 Velocity Measurement

Measurement Means	Application	Range, fpm	Precision	Limitations
Smoke puff or airborne solid tracer	Low air velocities in rooms; highly directional	5 to 50	10 to 20%	Awkward to use but valuable in tracing air movement
Deflecting-vane anemometer	Air velocities in rooms, at outlets, etc., directional	30 to 24,000	5%	Needs periodic check calibration
Revolving-vane anemometer	Moderate air velocities in ducts and rooms; somewhat directional	100 to 3000	2 to 5%	Extremely subject to error with variations in velocities with space or time; easily damaged; needs periodic calibration
Pitot tube	Standard instrument for measuring duct velocities	180 to 10,000 with micromanometer; 600 to 10,000 with draft gages; 10,000 up with manometer	1 to 5%	Accuracy falls off at low end of range
Impact tube and sidewall or other static tap	High velocities, small tubes and where air direction may be variable	120 to 10,000 with micromanometer; 600 to 10,000 with draft gages; 10,000 up with manometer	1 to 5%	Accuracy depends on constancy of static pressure across stream section
Heated thermocouple anemometer	Air velocities in ducts, velocity distributions	10 to 2000	3 to 20%	Accuracy of some types not good at lower end of range; steady-state measurements only
Hot-wire anemometer	a. Low air velocities; directional and nondirectional available	1 to 1000	2 to 5%	Requires accurate calibration at frequent intervals. Some are relatively costly.
	b. High air velocities	Up to 60,000	0.2 to 5%	
	c. Transient velocity and turbulence			

sufficient precision to solve many problems. Instruments that measure fluid velocity and their application range and precision are listed in Table 3.

Airborne Tracer Techniques

Tracer techniques are suitable for measuring velocity in an open space. Typical tracers include smoke, feathers, pieces of lint, and radioactive or nonradioactive gases. Measurements are made by timing the rate of movement of solid tracers or by monitoring the change in concentration level of gas tracers.

Smoke is a useful qualitative tool in studying air movements. Smoke can be obtained from titanium tetrachloride (irritating to nasal membranes) or by mixing potassium chlorate and powdered sugar (a nonirritating smoke) and firing the mixture with a match. The latter process produces considerable heat and should be confined to a pan away from flammable materials. The titanium tetrachloride smoke works well for spot tests, particularly for leakage through casings and ducts, because it can be handled easily in a small, pistol-like ejector.

The fumes of aqua ammonia and sulfuric acid, if permitted to mix, form a white precipitate. Two bottles, one containing ammonia water and the other containing acid, are connected to a common nozzle by rubber tubing. A syringe forces air over the liquid surfaces in the bottles; the two streams mix at the nozzle and form a white cloud.

A satisfactory test smoke also can be made by bubbling an airstream through ammonium hydroxide and then muriatic acid (Nottage *et al.* 1952). Smoke tubes, smoke candles, and smoke bombs are available for studying airflow patterns.

Deflecting Vane Anemometers

The deflecting vane anemometer consists of a pivoted vane enclosed in a case. Air exerts pressure on the vane as it passes through the instrument from an upstream to a downstream opening. A hair spring and a damping magnet resist vane movement. The instrument gives instantaneous readings of directional velocities on an indicating scale. With fluctuating velocities, it is necessary to average the needle swings visually to obtain average velocities. This instrument is useful for studying air motion in a room and in locating objectionable drafts; for measuring air velocities at supply and return diffusers and grilles; and for measuring laboratory hood face velocities.

Propeller or Revolving Vane Anemometers

The propeller anemometer consists of a light, revolving wind-driven wheel connected through a gear train to a set of recording dials that read linear feet of air passing in a measured length of time. It is made in various sizes—3, 4, and 6 in. are the most common. Each instrument requires individual calibration. At low velocities, the friction drag of the mechanism is considerable. To compensate for this, a gear train that overspeeds is commonly used. For this reason, the correction is often additive at the lower range and subtractive at the upper range, with the least correction in the middle range of velocities. The best of these instruments have starting speeds of 50 fpm or higher; therefore, they cannot be used below that air speed. Electronic revolving vane anemometers, with optical or magnetic pick-ups to sense the rotation of the vane, are available. Sizes for the vanes range as small as 1 in. in diameter for the electronic versions.

Cup Anemometers

The cup-type anemometer is primarily used to measure outdoor, meteorological wind speeds. It consists of three or four hemispherical cups mounted radially from a vertical shaft. Wind from any direction with a vector component in the plane of cup rotation causes the cups and shaft to rotate. Since the primary use of this type of instrument is to make meteorological wind speed measurements, the instrument is usually constructed so that wind speeds can be recorded or indicated electrically at a remote point.

Pitot-Static Tubes

The pitot-static tube, in conjunction with a suitable manometer or differential pressure transducer, provides a simple method of determining air velocity at a point in a flow field. Figure 5 shows the construction of a standard pitot tube (ASHRAE 1985) and the method of connecting it to a draft gage. The equation for determining air velocity from measured velocity pressure is

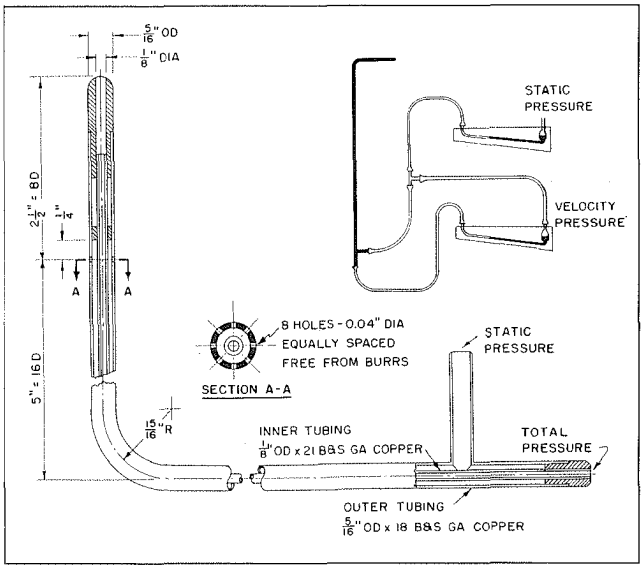

Fig. 5 Standard Pitot Tube

$$V = C\sqrt{p_w/\rho} \qquad (15)$$

where

V = velocity, fpm
p_w = velocity pressure (pitot-tube manometer reading), in. of water
ρ = density of air, lb/ft^3
C = 1096.5

The type of manometer or differential pressure transducer used with a pitot-static tube depends on the magnitude of velocity pressure being measured and the desired accuracy. At velocities greater than 1500 fpm, a draft gage of appropriate range is usually satisfactory. If the pitot-static tube is used to measure air velocities lower than 1500 fpm, a precision manometer or comparable pressure differential transducer is essential.

Other pitot-static tubes have been used and calibrated. To meet special conditions, various sizes of pitot-static tubes geometrically similar to the standard tube can be used. For relatively high velocities in ducts of small cross-sectional area, total pressure readings can be obtained with an impact (pitot) tube. Where static pressure across the stream is relatively constant, as in turbulent flow in a straight duct, a sidewall tap to obtain static pressure can be used with the impact tube to obtain the velocity pressure head. One form of impact tube is a small streamlined tube with a fine hole in its upstream end and with its axis placed parallel to the stream.

If the Mach number of the flow is greater than about 0.3, the effects of compressibility should be included in computing the air speed from pitot-static and impact (stagnation or pitot) tube measurements (Mease *et al.* 1992).

Thermal Anemometers

The thermal or hot-wire anemometer consists of a heated RTD, thermocouple junction, or thermistor sensor constructed at the end of a probe; it is designed to provide a direct, simple method of determining air velocity at a point in the flow field. The probe is placed into an airstream, and the movement of air past the electrically heated velocity sensor tends to cool the sensor in proportion to the speed of the airflow. The electronics and sensor are commonly combined into a portable, hand-held device that interprets the sensor signal and provides a direct reading of air velocity in either an analog or digital display format. Often the sensor probe also incorporates an ambient temperature-sensing RTD or thermistor, in which case the indicated air velocity is "temperature compensated" to "standard" air density conditions (typically 0.0748 lbs/ft^3).

Hot-wire anemometers have long been used in the fluid flow research field. Research anemometer sensors have been constructed using very fine wires in configurations that allow the researcher to characterize fluid flows in one, two, and three dimensions with sensor/electronics response rates up to several hundred kilohertz. This technology has been incorporated into more ruggedized sensors suitable for measurements in the HVAC field, primarily for unidirectional airflow measurement. Omnidirectional sensing instruments suitable for thermal comfort studies are also available.

The principal advantages of thermal anemometers are their wide dynamic range and their ability to sense extremely low velocities. The same instruments can measure air velocities up to 10,000 fpm and as low as 20 fpm. Typical accuracy (including repeatability) of 2 to 5% of reading over the entire velocity range is often achieved in commercially available portable instruments.

Among the limitations of thermal anemometers are the following: (1) the unidirectional sensor must be carefully aligned in the airstream (typically to within ±20° rotation) to achieve accurate results; (2) the velocity sensor must be kept clean because contaminant buildup will cause the calibration to change; and (3) due to the inherent high speed of response of thermal anemometers, measurements in turbulent flows can yield fluctuating velocity measurements. Electronically controlled time-integrated functions are now available in many digital air velocity meters to help smooth these turbulent flow measurements.

In the HVAC field, thermal anemometers are suitable for use in a variety of applications. They are particularly well-suited to the low velocities associated with laboratory fume hood face velocity measurements (typically in the 60 to 200 fpm range). Thermal anemometers can also be used for taking multipoint traverse measurements in ventilation duct work.

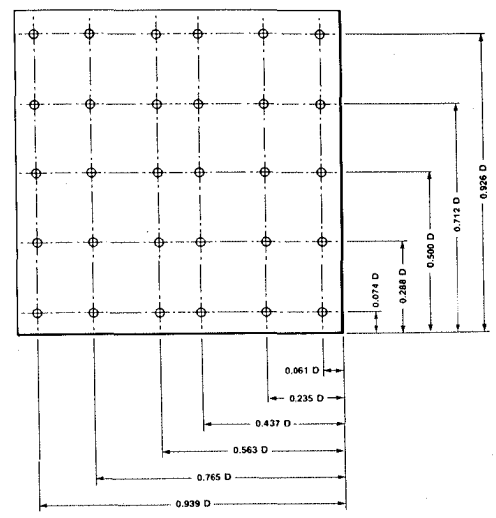
Measuring Flow in Ducts

Since velocity in a duct is seldom uniform across any section, and since a pitot tube reading or thermal anemometer indicates velocity at only one location, a traverse is usually made to determine average velocity. Generally, velocity is lowest near the edges or corners and greatest at or near the center.

To determine the velocity in the traverse plane, a straight average of individual point velocities will give satisfactory results when point velocities are determined by the log-Tchebycheff rule (ISO 3966). Figure 6 shows suggested sensor locations for traversing round and rectangular ducts. The log-Tchebycheff rule provides the greatest accuracy because its location of traverse points accounts for the effect of wall friction and the fall-off of velocity near the duct walls. For circular ducts, the log-Tchebycheff and log-linear traverse methods are similar. Log-Tchebycheff is now recommended for rectangular ducts as well. It minimizes the positive error (measured greater than actual) caused by the failure to account for losses at the duct wall. This error can occur when using the older method of equal subareas to traverse rectangular ducts.

For a rectangular duct traverse, a minimum of 25 points should be measured. For a duct side less than 18 in., locate the points at the center of equal areas not more than 6 in. apart, and use a minimum of 2 points per side. For a duct side greater than 56 in., the maximum distance between points is 8 in. For a circular duct traverse, the log-linear rule and three symmetrically disposed diameters may be used (Figure 6). Points on two perpendicular diameters may be used where access is limited.

If possible, measuring points should be located at least 7.5 diameters downstream and 3 diameters upstream from a disturbance (*i.e.*, caused by a turn). Compromised traverses as close as 2 diameters downstream and 1 diameter upstream can be per-



NO. OF POINTS OR TRAVERSE LINES	POSITION RELATIVE TO INNER WALL

Fig. 6 Measuring Points for Round and Rectangular Duct Traverse

formed with an increase in measurement error. Since field-measured airflows are rarely steady and uniform, particularly near disturbances, accuracy can be improved by increasing the number of measuring points. Straightening vanes (ASHRAE 1985) located 1.5 duct diameters ahead of the traverse plane improve measurement precision.

When velocities at a traverse plane fluctuate, the readings should be averaged on a time-weighted basis. Two traverse readings in short succession also help to average out velocity variations that occur with time. If negative velocity pressure readings are encountered, they are considered a measurement value of zero and calculated in the average velocity pressure. ASHRAE *Standard* 111 (1988) has further information on measuring flow in ducts.

Airflow-Measuring Hoods

Flow-measuring hoods are portable instruments designed to measure supply or exhaust airflow through diffusers and grilles in HVAC systems. A flow-measuring hood assembly typically consists of a fabric hood section, a plastic or metal base, an airflow-measuring manifold, a meter, and handles for carrying and holding the hood in place.

For volumetric airflow measurements, the flow-measuring hood is placed over a diffuser or grille. The fabric hood captures and directs airflow from the outlet or inlet across the flow-sensing manifold in the base of the instrument. The manifold consists of a number of tubes containing upstream and downstream holes in a grid pattern designed to simultaneously sense and average multiple velocity points across the base of the flow-measuring hood. Air from the upstream holes flows through the tubes, past a sensor, and then exits through the downstream holes. Sensors employed by different manufacturers include swinging vane anemometers, electronic micromanometers, and thermal anemometers. In the case of the electronic micromanometer sensor, air does not actually flow through the manifold, but the airtight sensor senses the pressure differential from the upstream to downstream series of holes. The meter on the base of the flow-measuring hood interprets the signal from the sensor and provides a direct reading of volumetric flow in either an analog or digital display format.

As a performance check in the field, the indicated flow of a measuring hood can be compared to a duct traverse flow measurement (using a pitot-tube or a thermal anemometer). All flow-measuring hoods induce some back pressure on the air-handling system, because the hood restricts the flow coming out of the diffuser. This added resistance alters the true amount of air coming out of the diffuser. In most cases, this error is negligible and is less than the accuracy of the instrument. When doing proportional balancing, this error need not be taken into account since all similar diffusers will have about the same amount of back pressure. To determine if back pressure is significant, a velocity traverse can be made in the duct ahead of the diffuser with and without the flow-measuring hood in place. The difference in the average velocity of the traverse indicates the degree of back-pressure compensation required on similar diffusers in the system. For example, if the average velocity is 800 fpm with the hood in place, and 820 fpm without the hood, the indicated flow reading can be multiplied by 1.025 on similar diffusers in the system (820/800 = 1.025). As an alternative, the designer of the air-handling system can predict the amount of airflow that is reduced because of the additional pressure of the hood by using a curve supplied by the flow-measuring hood manufacturer. This curve indicates the pressure drop through the hood for different flow rates.

Laser Doppler Velocimeter (or Anemometer)

The laser Doppler velocimeter (LDV) or laser Doppler anemometer (LDA) is an extremely complex system that collects scattered light produced by a particle passing through the intersection volume of two intersecting laser beams of the same light frequency (Mease *et al.* 1992). The scattered light consists of bursts containing a regularly spaced fringe pattern whose frequency is linearly proportional to the speed of the particle. Due to the cost and complexity of these systems, they are usually not

suitable for in situ field measurements. Rather, the primary application of LDV systems in the HVAC industry is to calibrate the calibration systems used to calibrate other air velocity instruments.

The greatest advantage of an LDV is its low-speed performance. It is capable of reading air speeds as low as 15 fpm with uncertainty levels of 1% or less (Mease *et al.* 1992). In addition, it is nonintrusive in the flow—only optical access is required. It can be used to measure fluctuating components as well as mean speeds and is available in one, two, and even three-dimensional configurations. Its biggest disadvantage is its high cost and extreme technological complexity, requiring highly skilled operators. Modern fiber optic systems require less skilled operators but at a considerable increase in cost.

FLOW RATE MEASUREMENT

Various means of measuring fluid flow rate are listed in Table 4. The values for volume or mass flow rate measurement (ASME 1971, Benedict 1984) are often determined by measuring pressure difference across an orifice, nozzle, or venturi tube. These types of meter have different advantages and disadvantages. For example, the orifice plate is more easily changed than the complete nozzle or venturi tube assembly. However, the nozzle is often preferred to the orifice because its discharge coefficient is more precise. The venturi tube is a nozzle followed by an expanding recovery section to reduce net pressure loss. Differential pressure-type flow measurement has benefited recently through workshops addressing fundamental issues, new textbooks, research, and improved standards (Miller 1983, DeCarlo 1984, Mattingly 1984, ASME 1985b, ASME 1988a, ASME 1988b, ASME 1991).

Fluid meters use a wide variety of physical techniques to make flow measurements (ASME 1971, Miller 1983, DeCarlo 1984); those more prevalently used are described in the following section. The search for high-accuracy flow measurement includes the arrangement of appropriate calibration procedures. While these used to be available only in calibration laboratories, they are now frequently purchased along with flowmeters so that flow measurements can be efficiently and effectively assured and validated at high levels of performance. To assure and validate calibration facilities and procedures, realistic traceability should be established and maintained for the calibration facilities and procedures. This is best done using round-robin testing programs (Mattingly 1985, Mattingly 1988, Benson *et al.* 1986, Olsen 1974).

Table 4 Volume or Mass Flow Rate Measurement

Measurement Means	Application	Range	Precision	Limitations
Orifice and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	1 to 5%	Discharge coefficient and accuracy influenced by installation conditions
Nozzle and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions
Venturi tube and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions
Rotameters	Used for liquids or gases	Any	0.5 to 5.0%	Should be calibrated for fluid with which used
Turbine flowmeters	Used for liquids or gases	Any	0.25 to 2.0%	Uses electronic readout
Timing given mass flow	Liquids or gases; used to calibrate other flowmeters	Any	0.1 to 0.5%	System is bulky and slow
Displacement meter	Relatively small volume flow with high pressure loss	As high as 1000 cfm depending on type	0.1 to 2.0% depending on type	Most types require calibration with fluid being metered
Gasometer or volume displacement	Short duration tests; used for calibrating other flowmeters	Total flow limited by available volume of containers	0.5 to 1.0%	—
Element of resistance to flow and differential pressure measurement system	Used for check where system has calibrated resistance element	Lower limit set by readable pressure drop	1 to 5%	Secondary reading depends on accuracy of calibration
Thomas meter (temperature rise of stream due to electrical heating)	Elaborate setup justified by need for good accuracy	Any	1%	Uniform velocity; usually used with gases
Heat input and temperature changes with steam and water coil	Check value in heater or cooler tests	Any	1 to 3%	—
Instrument for measuring velocity at point in flow	Primarily for installed systems where no special provision for low measurement has been made	Lower limit set by accuracy of velocity measurement	2 to 4%	Accuracy depends on uniformity of flow and completeness of traverse
Laminar flow element and differential pressure measurement system	Measure liquid or gas volume flow rate; nearly linear relationship with pressure drop; simple and easy to use	0.0001 to 2000 cfm	1%	Fluid must be free of dirt, oil, or other impurities, which could plug meter or affect its calibration
Magnetohydrodynamic flowmeter (electromagnetic)	Measures electrically conductive fluids, slurries; meter does not obstruct flow; no moving parts	0.1 to 10,0000 gpm	1%	At present state-of-the-art, conductivity of fluid must be greater than 5μmho/cm
Swirl flowmeter and vortex shedding meter	Measure liquid or gas flow in pipe; no moving parts	Above Reynolds number of 10^4	1%	—

Direct and Indirect Flow Measurement Methods

Both gas and liquid flow can be measured quite accurately by timing a collected amount of fluid that is determined gravimetrically or volumetrically. While this method is commonly used for calibrating other metering devices, it is particularly useful where the flow rate is low or intermittent and where a high degree of accuracy is required. These systems are generally large and slow, but in their simplicity, they can be considered primary devices.

The variable area meter or rotameter is a convenient direct reading flowmeter for liquids and gases. This is a vertical, tapered tube in which the flow rate is indicated by the position of a float suspended in the upward flow. The position of the float is determined by its buoyancy and the upwardly directed fluid drag.

Displacement meters measure total liquid or gas flow over time. The two major types of displacement meters used for gases are the conventional gas meter, which uses a set of bellows, and the wet test meter, which uses a water displacement principle.

The Thomas meter is used in laboratories to measure high gas flow rates with low pressure losses. The gas is heated by electric heaters, and the temperature rise is measured by two resistance thermometer grids. When the heat input and temperature rise are known, the mass flow of gas is calculated as the quantity of gas that will remove the equivalent heat at the same temperature rise.

A velocity traverse (made using a pitot tube or other velocity-measuring instrument) measures airflow rates in the field or calibrates large nozzles. This method can be imprecise at low velocities and impracticable where many test runs are in progress.

Another field-estimating method measures the pressure drop across elements with known pressure drop characteristics, such as heating and cooling coils or fans. If the pressure drop/flow rate relationship has been calibrated, the results can be precise. If the method depends on rating data, it should be used for check purposes only.

Venturi, Nozzle, and Orifice Flowmeters

Flow in a pipeline can be measured by a venturi meter (Figure 7), flow nozzle (Figure 8), or orifice plate (Figure 9). The American Society of Mechanical Engineers publication MFC-3M (ASME 1989) describes measurement of fluid flow in pipes using the orifice, nozzle, and venturi; the ASME Performance Test Code PTC 19.5-72 (ASME 1972) specifies their construction.

Assuming an incompressible fluid (liquid or slow-moving gas), uniform velocity profile, frictionless flow, and no gravitational effects, the principle of conservation of mass and energy can be applied to the venturi and nozzle geometries to give

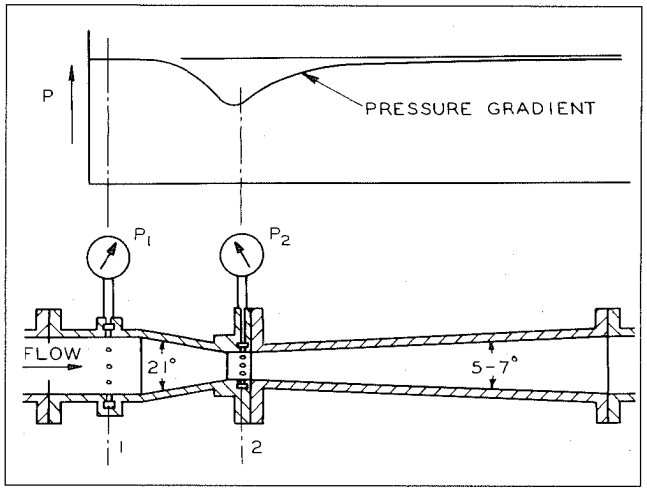

Fig. 7 Typical Herschel Type Venturi Meter

$$w = \rho V_1 A_1 = \rho V_2 A_2 = A_2 \sqrt{\frac{2g\rho\,(p_1 - p_2)}{1 - \beta^4}} \qquad (16)$$

where

w = flow rate, lb/s
V = velocity of stream, ft/s
A = flow area, ft^2
g = gravitational factor = 32.174 ft/s^2
ρ = density of fluid, lb/ft^3
p = absolute pressure, lb/ft^2
β = (D_2/D_1) for venturi and sharp edge orifice and d/D for flow nozzle

Note: Subscript 1 refers to the entering conditions; subscript 2 refers to the throat conditions.

Since the flow through the meter is not frictionless, a correction factor C is defined to account for friction losses. If the fluid is at a high temperature, an additional correction factor F_a should be included to account for thermal expansion of the primary element. Since this amounts to less than 1% at 500°F, it can usually be omitted. Equation (16) then becomes

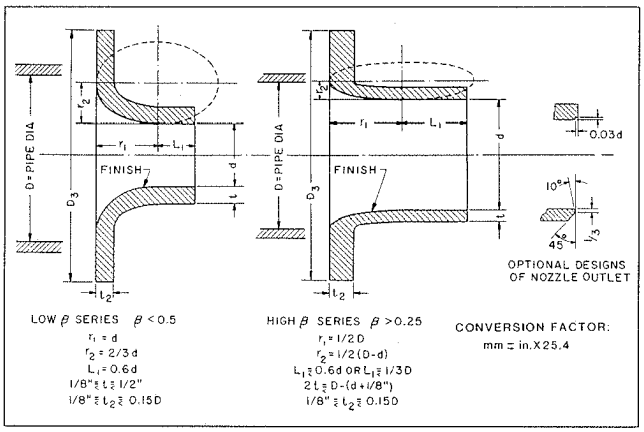

Fig. 8 Dimensions of ASME Long Radius Flow Nozzles
(Use of either recess or bevel at nozzle outlet is optional)

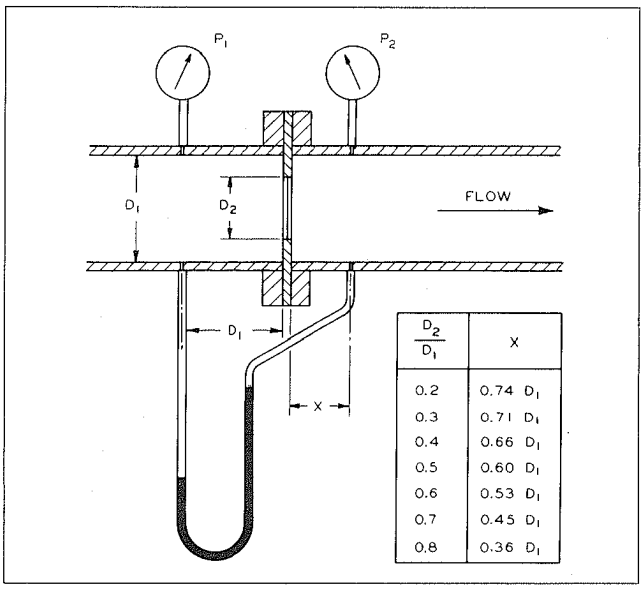

Fig. 9 Sharp Edge Orifice with Pressure Tap Locations
From ASME PTC 19.5. Reprinted with permission of ASME.

$$w = CA_2\sqrt{2g\rho\,(p_1 - p_2)/(1 - \beta^4)} \quad (17)$$

where Q is the discharge rate in ft³/s.

The factor C is a function of geometry and Reynolds number. Values of C are given in ASME PTC 19.5-72. The approach factor, $1/\sqrt{1-\beta^4}$, can be combined with the discharge coefficient, as described later. The jet passing through an orifice plate contracts to a minimum area at the vena contracta located a short distance downstream from the orifice plate. The contraction coefficient, energy loss coefficient, and approach factor can be combined into a single constant K, which is a function of geometry and Reynolds number. The orifice flow rate equations then become

$$Q = KA_2\sqrt{2g\rho\,(p_1 - p_2)} \quad (18)$$

where

Q = discharge, ft³/s
A_2 = orifice area, ft²
$p_1 - p_2$ = pressure drop in lb/ft² as obtained by pressure taps

Values of K are shown in ASME PTC 19.5-72.

Valves, bends, and fittings upstream from the flowmeter can cause errors. Long, straight pipes should be installed upstream and downstream from the flow devices to assure fully developed flow for proper measurement. ASHRAE *Standard* 41.8 specifies upstream and downstream pipe lengths for measuring flow of liquids with an orifice plate. ASME PTC 19.5-72 gives the piping requirements between various fittings and valves and the venturi, nozzle, and orifice. If these conditions cannot be met, flow conditioners or straightening banes can be used (ASME 1972, ASME 1988b, Mattingly 1984, Miller 1983).

Compressibility effects must be considered for gas flow if the pressure drop across the measuring device is more than a few percent of the initial pressure.

Nozzles are sometimes arranged in parallel pipes from a common manifold; thus, the capacity of the testing equipment can be changed by shutting off the flow through one or more nozzles. An apparatus designed for testing airflow and capacity of air-conditioning equipment is described by Wile (1947), who also presents pertinent information on nozzle discharge coefficients, Reynolds numbers, and resistance of perforated plates. Some laboratories refer to this apparatus as a code tester.

Variable Area Flowmeters (Rotameters)

In permanent installations where high precision, ruggedness, and operational ease are important, the variable area flowmeter is satisfactory. It is frequently used to measure liquids or gases in small-diameter pipes. For ducts or pipes over 6 in. in diameter, the expense of this meter may not be warranted. In larger systems, however, the meter can be placed in a bypass line and used with an orifice.

The variable area meter (Figure 10) commonly consists of a float that is free to move vertically in a transparent tapered tube. The fluid to be metered enters at the narrow bottom end of the tube and moves upward, passing at some point through the annulus formed between the float and the inside wall of the tube. At any particular flow rate, the float assumes a definite position in the tube; a calibrated scale on the tube shows the float's location and the fluid flow rate.

The position of the float is established by a balance between the fluid pressure forces across the annulus and gravity on the float. The buoyant force supporting the float, $v_f(\rho_f - \rho)$, is balanced by the pressure difference acting on the cross-sectional area of the float $A_f\Delta p$, where ρ_f, A_f, v_f, are, respectively, the float density,

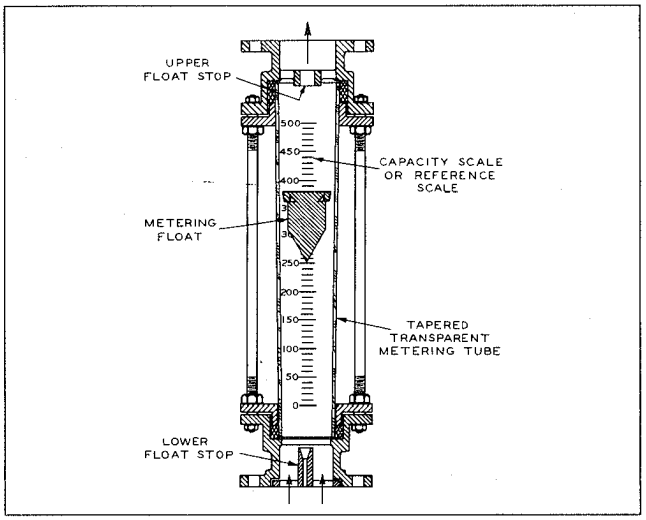

Fig. 10 Variable Area Flowmeter

float cross-sectional area, and float volume. The pressure difference across the annulus is

$$\Delta p = v_f(\rho_f - \rho)/A_f \quad (19)$$

The mass flow follows from Equation (14) as

$$w = KA_2\sqrt{2gv_f(\rho_f - \rho)\,\rho/A_f} \quad (20)$$

The flow for any selected fluid is nearly proportional to the area, so that calibration of the tube is convenient. To use the meter for different fluids, the flow coefficient variation for any float must be known. Float design can reduce variation of the flow coefficient with Reynolds number; float materials can reduce the dependence of mass flow calibration on fluid density.

Turbine Flowmeters

Turbine flowmeters are volumetric flow rate sensing meters with a magnetic stainless steel turbine rotor suspended in the flow stream of a nonmagnetic meter body. The fluid stream exerts a force on the blades of the turbine rotor, setting it in motion and converting the fluid's linear velocity to an angular velocity. Design motivation for turbine meters is to have the rotational speed of the turbine proportional to the average fluid velocity and thus to the volume rate of fluid flow (Miller 1983, DeCarlo 1984, Mattingly 1992).

The rotational speed of the rotor is monitored by an externally mounted pickoff assembly. Magnetic and radio frequency are the most commonly used pickoffs. The magnetic pickoff contains a permanent magnet and coil. As the turbine rotor blades pass through the field produced by the permanent magnet, a shunting action induces ac voltage in the winding of the coil wrapped around the magnet. A sine wave with a frequency proportional to the flow rate develops. With the radio frequency pickoff, an oscillator applies a high-frequency carrier signal to a coil in the pickoff assembly. The rotor blades pass through the field generated by the coil and modulate the carrier signal by shunting action on the field shape. The carrier signal is modulated at a rate corresponding to the rotor speed, which is proportional to the flow rate. With both pickoffs, frequency of the pulses generated becomes a measure of flow rate, and the total number of pulses measures total volume (Woodring 1969, Shafer 1961, Mattingly 1992).

Since output frequency of the turbine flowmeter is proportional to flow rate, every pulse from the turbine meter is equivalent to a

known volume of fluid that has passed through the meter; the sum of these pulses yields total volumetric flow. Totalization is accomplished by electronic counters designed for use with turbine flowmeters; they combine a mechanical or electronic register with the basic electronic counter.

Turbine flowmeters should be installed with straight lengths of pipe upstream and downstream from the meter. The length of the inlet and outlet pipes should be according to manufacturers' recommendations or to pertinent standards. Where recommendations on standards cannot be accommodated, the meter installation should be calibrated. Some turbine flowmeters can be used in bidirectional flow applications. A fluid strainer, used with liquids of poor or marginal lubricity, minimizes bearing wear.

The lubricity of the process fluid and the type and quality of rotor bearings determine whether the meter is satisfactory for the particular application. When choosing turbine flowmeters for use with fluorocarbon refrigerants, attention must be paid to the type of bearings used in the meter and to the oil content of the refrigerant. For these applicants, sleeve-type rather than standard ball bearings are recommended. The amount of oil in the refrigerant can severely affect calibration and bearing life.

In metering liquid fluorocarbon refrigerants, the liquid must not flash to a vapor (cavitate). This would cause a tremendous increase in flow volume. Flashing results in erroneous measurements and rotor speeds that can damage the bearings or cause a failure. Flashing can be avoided by maintaining an adequate back pressure on the downstream side of the meter (Liptak 1972).

Positive Displacement Meters

Many positive displacement meters are available for measuring total liquid or gas volume flow rates. The fluid measured in these meters flows progressively into compartments of definite size. As the compartments are filled, they are rotated so that the fluid discharges from the meter. The flow rate through the meter is equal to the product of the compartment size, the number of compartments, and the rotation rate of the rotor. Most of these meters have a mechanical register, calibrated to show total flow.

ELECTRIC MEASUREMENT

Ammeters

Ammeters are low-resistance instruments for measuring current. They should be connected in series with the circuit being measured (Figure 11). Ideally, they have the appearance of a short circuit, but in practice, all ammeters have a nonzero input impedance that influences the measurement to some extent.

Ammeters often have several ranges, and it is good practice to start with the highest range when measuring unknown currents and then reduce the range to the appropriate value to obtain the most sensitive reading. Ammeters with range switches maintain circuit continuity during switching. On some older instruments, it may be necessary to short-circuit the ammeter terminals when changing the range.

Current transformers are often used to increase the operating range of ammeters. They may also provide isolation and thus protection from a high-voltage line. Current transformers have at least two separate windings on a magnetic core (Figure 12). The primary winding is connected in series with the circuit in which the current is measured. In the case of a "clamp-on" probe, the transformer core is actually opened and then connected around a single conductor carrying the current to be measured. That conductor serves as the primary winding. The secondary winding carries a scaled down version of the primary current, which is connected to an ammeter. Depending on the type of instrument, the ammeter reading may have to be multiplied by the ratio of the transformer.

When using an auxiliary current transformer, the secondary circuit must not be open when current is flowing in the primary winding; dangerous high voltage may exist across the secondary terminals. A short-circuiting blade between the secondary terminals should be closed before the secondary circuit is opened at any point.

Transformer accuracy can be impaired by the residual magnetism in the core when the primary circuit is opened at an instant when the flux is large. The transformer core may be left magnetized, resulting in ratio and phase angle errors. The primary and secondary windings should be short-circuited before making changes.

Voltmeters

Voltmeters are high-resistance instruments that should be connected across the load (in parallel), as shown in Figure 13. Ideally they have the appearance of an open circuit, but in practice, all voltmeters have some finite impedance that influences the measurement to some extent.

Voltage transformers are often used to increase the operating range of a voltmeter (Figure 14). They also provide isolation from high voltages and prevent injury to the operator. Like current transformers, voltage transformers consist of two or more windings on a magnetic core. The primary winding is generally connected across the high voltage to be measured, and the secondary winding is connected to the voltmeter. Unlike current transformers, it is important not to short-circuit the secondary winding of a voltage transformer.

Wattmeters

Wattmeters are instruments that measure the active power of an ac circuit, which equals the voltage multiplied by that part of the current in phase with the voltage. There are generally two sets of terminals—one to connect the load voltage and the other to connect in series with the load current. Current and voltage transformers can be used to extend the range of a wattmeter or to isolate it from high voltage. Figures 15 and 16 show connections for single-phase wattmeters, and Figure 17 shows use of current and voltage transformers with a single-phase wattmeter.

Wattmeters with multiple current and voltage elements are available to measure polyphase power. Polyphase wattmeter connections are shown in Figures 18 and 19.

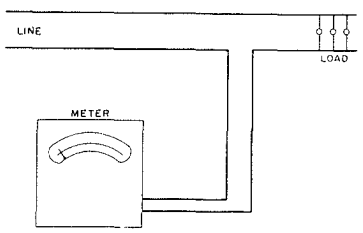

Fig. 11 Ammeter Connected in Power Circuit

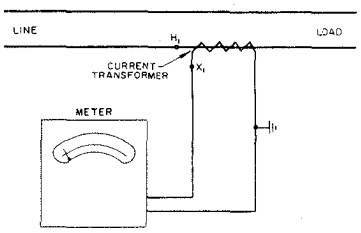

Fig. 12 Ammeter with Current Transformer

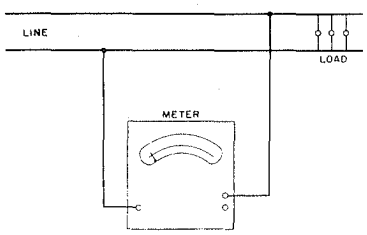

Fig. 13 Voltmeter Connected Across Load

Power-Factor Meters

Power-factor meters measure the ratio of the active power to the apparent power (product of the voltage and current). The connections for power-factor meters and wattmeters are similar, and current and voltage transformers can be used to extend their range. Connections for single-phase and polyphase power-factor meters are shown in Figures 20 and 21, respectively.

HUMIDITY MEASUREMENT

Many instruments are available for measuring the moisture content of air. The indication sensors used on the instruments respond to different moisture property contents. These responses are related to factors such as wet-bulb temperature, relative humidity, humidity (mixing) ratio, dew point, and frost point.

Table 5 lists instruments for measuring humidity. Each is capable of accurate measurement under certain conditions and within specific limitations. The following sections describe various instruments used to measure humidity.

Psychrometers

Any instrument capable of measuring the humidity or psychrometric state of air is a hygrometer. A typical industrial psychrometer consists of a pair of matched electrical or mechanical temperature sensors, one of which is kept wet with a moistened wick. A blower aspirates the sensor, which lowers the temperature at the moistened temperature sensor. The lowest temperature depression occurs when the evaporation rate required to saturate the moist air adjacent to the wick is constant. This is a steady-state, open-loop, nonequilibrium process, which depends on the purity of the water, cleanliness of the wick, ventilation rate, radiation effects, size and accuracy of the temperature sensors, and the transport properties of the gas.

ASHRAE *Standard* 41.6-1992R recommends an airflow over both the wet and dry bulbs of 600 to 1000 fpm for transverse ventilation and 300 to 500 fpm for axial ventilation.

The sling psychrometer consists of two thermometers mounted side by side in a frame fitted with a handle for whirling the device through the air. The thermometers are spun until their readings become steady. In the ventilated or aspirated psychrometer, the thermometers remain stationary, and a small fan, blower, or syringe moves the air across the thermometer bulbs. Various designs are used in the laboratory, and commercial models are available.

Other temperature sensors, such as thermocouples and thermistors, are also used and can be adapted for recording temperatures

Table 5 Humidity Sensor Properties

Type of Sensor	Sensor Category	Method of Operation	Approximate Range	Some Uses	Approximate Accuracy
Dunmore type	Electrical	Impedance	7 to 98% rh at 40 to 140°F	Measurement, control	±1.5% rh
Surface acoustic wave	Electrical	SAW Attenuation	85 to 98% rh	Measurement, control	±1% rh
Ion exchange resin	Electrical	Impedance or capacitance	10 to 100% rh at −40 to 190°F	Measurement, control	±5% rh
Aluminum oxide	Electrical	Capacitance	5 to 100% rh	Measurement, control	±3% rh
Aluminum oxide	Electrical	Capacitance	−110 to 140°F dp	Trace moisture measurement, control	±2°F dp
Porous ceramic	Electrical	Impedance or capacitance			
Electrolytic hygrometer	Electrical	Capacitance			
Infrared laser diode	Electrical	Optical diodes	0.1 to 100 ppm	Trace moisture measurement	±0.1 ppm
Hair	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Cellulosic materials	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Nylon	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Dacron thread	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Goldbeaters skin	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Carbon sensor	Mechanical	Dimensional change	5 to 100% rh	Measurement	±5% rh
Piezoelectric	Mass sensitive	Mass changes due to adsorbed moisture	−100 to 0°F	Trace moisture measurement, control	±2 to ±10°F dp
Color change	Physical	Color changes	10 to 80% rh	Warning device	±10% rh
Chilled mirror	Dew point	Optical determination of moisture formation	−110 to 200°F dp	Measurement, control, meteorology	±0.4 to ±4°F
Heated saturated salt solution	Water vapor pressure	Vapor pressure depression in salt solution	−20 to 160°F dp	Measurement, control, meteorology	±3°F
Gravimetric	Direct measurement of mixing ratio	Comparison of sample gas with dry airstream	0.12 g/kg to 20g/kg mixing ratio	Primary standard, research and laboratory	±0.13% of reading
Coulometric	Electrolytic cell	Electrolyses due to adsorbed moisture	1 to 1000 ppm	Measurement	
Psychrometer	Evaporative cooling	Temperature measurement of wet bulb	32 to 180°F	Measurement, standard	±3% to ±7% rh
Adiabatic saturation psychrometer	Evaporative cooling	Temperature measurement of thermodynamic wet bulb	40 to 85°F	Measurement, standard	±0.2% to ±2% rh
Radiation absoption	Moisture absorption	Moisture adsorption by UV or IR radiation	0 to 180°F dp	Measurement, control, meteorology	±4°F dp, ±5%

Notes:
1. This table does not encompass all of the available technology for the measurement of humidity.
2. The approximate range for the device types listed is based on surveys of device manufacturers.
3. The approximate accuracy is based on manufacturers' data.
4. Presently the National Institute of Standards and Technology (NIST) will only certify instruments whose operating range is within −75 to 100°C dew point.

or for use where a small instrument is required. Small-diameter wet-bulb sensors operate with low ventilation rates.

Charts and tables showing the relationship between the temperatures and humidity are available. Data are usually based on a barometric pressure equal to one standard atmosphere. To meet special needs, charts can be produced that apply to nonstandard pressure, *e.g.*, the ASHRAE 7500-ft chart. Alternatively, mathematical calculations can be made (Kusuda 1965). Uncertainties of ±3 to ±7% rh are typical for psychrometer-based derivation. The degree of uncertainty is a function of the accuracy of the temperature measurements, wet and dry bulb, knowledge of the barometric pressure, and conformance to accepted operational procedures such as those outlined in ASHRAE *Standard* 41.6.

In air temperatures below 32°F, the water on the wick may either freeze or supercool. Since the wet-bulb temperature is different for ice and water, its state must be known and a proper chart or table used. Some operators remove the wick from the wet-bulb for freezing conditions and dip the bulb in water a few times; this allows water to freeze on the bulb between dips, forming a film of ice. Since the wet-bulb depression is slight at low temperatures, precise temperature readings are essential. A psychrometer can be used at high temperatures, but, if the wet-bulb depression is large, the wick must remain wet and water supplied to the wick must be cooled so as not to influence the wet-bulb temperature by carrying sensible heat to it (Richardson 1965, Worrall 1965).

Greenspan and Wexler (1968) and Wentzel (1961) have developed devices to measure adiabatic saturation temperature.

Dew-Point Hygrometers

Chilled mirror dew-point hygrometer. The condensation-type (chilled mirror) dew-point hygrometer is an accurate and reliable instrument, with a wide humidity range. However, these features are obtained through an increase in complexity and cost when compared to the psychrometer. In the condensation-type hygrometer, a surface is cooled (thermoelectrically, mechanically, or chemically) until dew or frost begins to condense out. The condensate surface is maintained electronically in vapor pressure equilibrium with the surrounding gas, while surface condensation

is detected by optical, electrical, or nuclear techniques. The measured surface temperature is then the dew-point temperature.

The largest source of error in a condensation hygrometer stems from the difficulty in measuring condensate surface temperature accurately. Typical industrial versions of the instrument are accurate to ±1.0°F over wide temperature spans. With proper attention to the condensate surface temperature measuring system, errors can be reduced to about ±0.4°F. Condensation-type hygrometers can be made surprisingly compact using solid-state optics and thermoelectric cooling.

Wide-span and minimal errors are two of the main features of this instrument. A properly designed condensation hygrometer can measure dew points from 200°F down to frost points of −100°F. Typical condensation hygrometers can cool to 150°F below the ambient temperature, establishing lower limits of the instrument to dew points corresponding to approximately 0.5% rh. Accuracies for measurements above −40°F can be ±2°F or better, deteriorating to ±4°F at lower temperatures.

The response time of a condensation dew-point hygrometer is usually specified in terms of its cooling/heating rate, typically 4°F/s for thermoelectric cooled mirrors. This makes it somewhat faster than a heated salt hygrometer. Perhaps the most significant feature of the condensation hygrometer is its fundamental measuring technique, which essentially renders the instrument self-calibrating. For calibration, it is only necessary to manually override the surface cooling control loop, causing the surface to heat, and witness that the instrument recools to the same dew point when the loop is closed. Assuming that the surface temperature measuring system is correct, this is a reasonable check on the instrument's performance.

Although condensation hygrometers can become contaminated, they can easily be cleaned and returned to service with no impairment in performance.

Salt-phase heated hygrometer. Another instrument in which the temperature varies with ambient dew-point temperature is variously designated as a self-heating, salt-phase transition or heated electrical hygrometer. This device usually consists of a tubular substrate covered by glass fiber fabric, with a spiral bifilar winding for electrodes. The surface is covered with a salt solution—usually lithium chloride. The sensor is connected in series with a ballast and a 24-V (ac) supply. When in operation, electrical current flowing through the salt film heats the sensor. The electrical resistance characteristics of the salt are such that a balance is reached with the salt and its critical moisture content, corresponding to a saturated solution. The sensor temperature adjusts automatically so that the water vapor pressures of the salt film and ambient atmosphere are equal. With lithium chloride, this sensor cannot be used to measure relative humidity below approximately 12% (the equilibrium relative humidity of this salt), and it has an upper dew-point limit of about 160°F. The regions of highest precision are between −10 and 93°F, and above 105°F dew point. Another problem is that of the lithium chloride solution being washed off when exposed to water. In addition, this type of sensor is subject to contamination problems, which limits its accuracy. Its response time is also very slow; it takes approximately 2 min for a 67% step change.

Mechanical Hygrometers

Many organic materials change in dimension with changes in humidity; this action is used in a number of simple and effective humidity indicators, recorders, and controllers (see Chapter 41 of the 1992 ASHRAE *Handbook—Systems and Equipment*). They are coupled to pneumatic leakports, mechanical linkages, or electrical transduction elements to form hygrometers.

Commonly used organic materials are human hair, nylon, dacron, animal membrane, animal horn, wood, and paper. Their inherent nonlinearity and hysteresis must be compensated for within the hygrometer. These devices are generally unreliable below 32°F. The response is generally inadequate for monitoring a changing process. Responses can be affected significantly by exposure to extremes of humidity. Such devices require initial calibration and frequent recalibration; however, they are useful, because they can be arranged to read directly in terms of relative humidity, and they are simpler and less expensive than most other types.

Electrical Impedance Hygrometers

Many substances adsorb or lose moisture with changing relative humidity and exhibit corresponding changes in electrical impedance.

Dunmore hygrometers. This sensor consists of dual electrodes on a tubular or flat substrate; it is coated with a film containing salt, such as lithium chloride, in a binder to form an electrical connection between windings. The relation of sensor resistance to humidity is usually represented by graphs. Since the sensor is highly sensitive, the graphs are a series of curves, each for a given temperature, with intermediate values found by interpolation. Several resistance elements, called Dunmore elements, cover a standard range. Systematic calibration is essential, since the resistance grid varies with time and contamination as well as with exposure to temperature and humidity extremes.

Polymer film electronic hygrometers. These devices have a hygroscopic organic polymer, which is deposited with thin or thick film-processing technology on a water permeable substrate. Both capacitance and impedance sensors are available. The impedance devices are composed of either ionic or electronic conduction types. These hygrometers typically have integrated circuits that provide temperature correction and signal conditioning. The primary advantages of this sensor technology are small size, low cost, and fast response times in the order of 1 to 120 s for 64% change in relative humidity.

Ion exchange resin electric hygrometers. A conventional ion exchange resin consists of a polymer with a high relative molecular mass and having polar groups of positive or negative charge in cross-link structure. Associated with these polar groups are ions of opposite charge that are held by electrostatic forces to the fixed polar groups. In the presence of water or water vapor, the electrostatically held ions become mobile; thus, when a voltage is impressed across the resin, the ions are capable of electrolytic conduction. The Pope cell is one example of an ion exchange element. It is a wide-range sensor, typically covering 15 to 95% rh. Therefore, one sensor can be used where several Dunmore elements would be required. The Pope cell, however, has a nonlinear characteristic from approximately 1000 ohms at 100% rh to several megohms at 10% rh.

Impedance-based porous ceramic electronic hygrometers. Utilizing the adsorption characteristics of oxides, humidity-sensitive ceramic oxide devices use either ionic or electronic measurement techniques to relate adsorbed water to relative humidity. Ionic conduction is produced by dissociation of water molecules forming surface hydroxyls. The dissociation causes migration of protons such that device impedance decreases with increasing water content. The ceramic oxide is sandwiched between porous metal electrodes that connect the device to an impedance-measuring circuit for linearizing and signal conditioning. These sensors have excellent sensitivity, resistance to contamination, high temperature (up to 400°F), and may get fully wet without sensor degradation. These sensors are accurate to about ±1.5% and ±1% rh when temperature compensated. These sensors have a moderate cost.

Aluminum oxide capacitive sensor. This sensor consists of an aluminum strip that is anodized by a process that forms a porous oxide layer. A very thin coating of gold is then evaporated over this structure. The aluminum base and the gold layer form the two electrodes of what is essentially an aluminum oxide capacitor.

Water vapor is rapidly transported through the gold layer and equilibrates on the pore walls in a manner functionally related to the vapor pressure of water in the atmosphere surrounding the sensor. The number of water molecules adsorbed on the oxide structure determines the capacitance between the two electrodes.

Electrolytic Hygrometers

In electrolytic hygrometers, air is passed through a tube where moisture is adsorbed by a highly effective desiccant, usually phosphorous pentoxide, and electrolyzed. The airflow is regulated to 0.0035 cfm at a standard temperature and pressure. As the incoming water vapor is absorbed by the desiccant and electrolyzed into hydrogen and oxygen, the current of electrolysis determines the mass of water vapor entering the sensor. The flow rate of the entering gas is controlled precisely to maintain a standard sample mass flow rate into the sensor. The instrument is usually designed for use with moisture-air ratios in the range of less than 1 to 1000 ppm, but can be used with higher humidities.

Piezoelectric sorption. This hygrometer compares the changes in frequency of two hygroscopically coated quartz crystal oscillators. As the mass of the crystal changes due to the absorption of water vapor, the frequency changes. The amount of water sorbed on the sensor is a function of relative humidity, *i.e.*, partial pressure of water as well as the ambient temperature.

A commercial instrument uses a hygroscopic polymer coating on the crystal. The humidity is measured by monitoring the vibration frequency change of the quartz crystal when the crystal is alternately exposed to wet and dry gas.

Radiation Absorption (Infrared/Ultraviolet)

Radiation absorption devices operate on the principle that selective absorption of radiation is a function of frequency for different mediums. Water vapor absorbs infrared radiation at 2 to 3 μm wavelengths and ultraviolet radiation centered about the Lyman-alpha line at 0.122 μm. The amount of absorbed radiation is directly related to the absolute humidity or water vapor content in the gas mixture according to Beer's law. The basic unit consists of an energy source and optical system for isolating wavelengths in the spectral region of interest, and a measurement system for determining the attenuation of radiant energy caused by the water vapor in the optical path. The adsorbed radiation is measured extremely fast and independent of the degree of saturation of the gas mixture. Response times of 0.1 to 1 s for 90% change in moisture content is common. Spectroscopic hygrometers are primarily used where a noncontact application is required; this may include atmospheric studies, industrial drying ovens, and harsh environments. The primary disadvantages of this device are its high cost and relatively large size.

Gravimetric Hygrometers

Humidity levels can be measured by extracting and weighing water vapor in a known quantity or atmosphere. For precise laboratory work, powerful desiccants, such as phosphorous pentoxide and magnesium perchlorate, are used for the extraction process; for other purposes, calcium chloride or silica gel are satisfactory.

When the highest level of accuracy is required, the gravimetric hygrometer, developed and maintained by NIST, is the ultimate in the measurement hierarchy. The gravimetric hygrometer yields and determines the absolute water vapor content, where the mass of the absorbed water and the precise measurement of the gas volume associated with the water vapor determine the mixing ratio or absolute humidity of the sample. This system has been chosen as the primary standard, because the required measurement of mass, temperature, pressure, and volume can be made with extreme precision. However, its complexity and required attention to detail limit its usefulness.

Calibration

The need for recalibration for many hygrometers depends on the accuracy required, on the stability of the sensor, and on the conditions to which the sensor is being subjected. Many hygrometers should be calibrated regularly by exposure to an atmosphere maintained at a known humidity and temperature, or by comparison with a transfer standard hygrometer. Complete calibration usually requires observation of a series of temperatures and humidities. Methods for producing known humidities include saturated salt solutions (Greenspan 1976, Huang and Whetstone 1985), sulfuric acid solutions, and mechanical systems, such as the divided flow, two-pressure (Amdur 1965), two-temperature (Till and Handegord 1960), and the NIST two-pressure humidity generator (Hasegawa 1976). All these systems rely on precise methods of temperature and pressure control within a controlled environment to produce a known humidity, usually with accuracies of ± 0.5 to ± 1.0%. The operating range for the precision generator is typically 5 to 95% rh.

SOUND AND VIBRATION MEASUREMENT

Measurement systems for determining sound pressure, sound intensity, and mechanical vibration generally involve the use of transducers to convert mechanical signals into electrical signals, which are then processed electronically in order to characterize the measured mechanical signals. These measurement systems contain one or more of the following elements which may, or may not, be contained in a single instrument:

1. A transducer, or an assembly of transducers, to convert sound pressure, sound intensity, or mechanical vibration (either time-varying strain, displacement, velocity, acceleration, or force) into an electrical signal that is quantitatively related to the mechanical quantity being measured.
2. Amplifiers and networks to provide such functions as electrical impedance matching, signal conditioning, integration, differentiation, frequency weighting, and gain.
3. Signal-processing equipment to detect and quantify those aspects of the signal that are being measured (peak value, rms value, time-weighted average level, power spectral density, or magnitude or phase of a complex linear spectrum or transfer function).
4. A device, such as a meter, oscilloscope, digital display, or level recorder, to display the signal or the aspects of it that are being quantified.

The relevant range of sound and vibration signals can vary over more than 12 orders of magnitude in amplitude and more than 8 orders of magnitude in frequency, depending on the application. References on instrumentation, measurement procedures, and signal analysis are given in the bibliography. Product and application notes, technical reviews, and books published by instrumentation manufacturers are an excellent source of additional reference material. See Chapter 7 for further information on sound and vibration.

Sound Measurement

A microphone is an electroacoustical transducer that transforms an acoustical signal into an electrical signal. The two predominant transduction principles used to measure sound (as opposed to broadcast or record) are the electrostatic and piezoelectric. Electrostatic (capacitor) microphones are available either as electric microphones, which do not require an external polarizing voltage, or as condenser microphones, which do require an external polarizing voltage, typically in the range of 28 to 200 V (dc). Piezoelectric microphones may be manufactured using either natural piezoelectric crystals or poled ferroelectric crystals. The

types of response characteristics of measuring microphones are pressure, free field, and random incidence (diffuse field). A microphone with a uniform pressure response characteristic maintains uniform sensitivity over its operating frequency range when exposed to a sound pressure that is uniform over the surface of the sensing element. A microphone with a uniform free-field response characteristic maintains uniform sensitivity over its operating frequency range when exposed to a plane progressive sound wave at a specified angle of incidence to the surface of the sensing element. A microphone with a uniform random-incidence response characteristic maintains uniform sensitivity over its operating frequency range when exposed to a diffuse sound field. The sensitivity and the frequency range over which the microphone has uniform sensitivity (flat frequency response) vary with the diameter (surface area) of the sensing element and the microphone type. Other factors that may critically affect the performance or response of a measuring microphone and preamplifier in a given measurement application are atmospheric pressure, temperature, relative humidity, external magnetic and electrostatic fields, mechanical vibration, and radiation. A microphone should be selected based on its long- and short-term stability; its performance characteristics (sensitivity, frequency response, amplitude linearity, self-noise, etc.) versus the expected amplitude of sound pressure, frequency, range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations, such as size and directional characteristics.

Microphone preamplifiers, amplifiers, weighting networks (see Chapter 7), filters, and displays are available as separate components, or as an integral part of a measuring instrument, such as a sound level meter, personal noise exposure meter, measuring amplifier, or real-time fractional octave or Fourier (*e.g.*, FFT) signal analyzer. Which instrument(s) to include in a sound measurement system depends on the purpose of the measurement and the frequency range and resolution of signal analysis. In the case of community and industrial noise measurements for regulatory purposes, the instrument, signal processing, and quantity to be measured are usually dictated by the pertinent regulation. Acoustical measurements made to quantify other parameters, characteristics, or criteria [*e.g.*, sound power in HVAC ducts, sound power emitted by machinery, noise criteria (NC) numbers, sound absorption coefficients, sound transmission loss of building partitions, reverberation times (T_{60}), etc.] will generally each dictate a different set of optimal instrumentation.

Measurement criteria often dictate the use of filters to perform signal analysis in the frequency domain in order to indicate the spectrum of the sound being measured. Filters of different bandwidths for different purposes include fractional octave band (one, one-third, one-twelfth, etc.), constant percentage bandwidth, and constant (typically narrow) bandwidth. The filters may be analog or digital and, if digital, may, or may not, be capable of real-time data acquisition during the measurement period, depending on the bandwidth of frequency analysis. FFT signal analyzers are generally used in situations that require very narrow-band signal analysis when the amplitudes of the sound spectra vary significantly with respect to frequency. This may occur in regions of resonance or when it is necessary to identify narrow-band or discrete sine-wave signal components of a spectrum in the presence of other such components or of broad-band noise.

Special rooms and procedures are required to characterize and calibrate sound sources and receivers. These rooms are generally classified into three types—anechoic, semianechoic, and reverberant. The ideal anechoic room or chamber would have boundary surfaces that completely absorb sound energy at all frequencies. The ideal semianechoic room or chamber would be identical to the ideal anechoic room, except that one surface would totally reflect sound energy at all frequencies. The ideal reverberant room or chamber would have boundary surfaces that totally reflect sound energy at all frequencies.

Anechoic chambers are used to perform measurements under conditions approximating those of a free sound field. They can be used in calibrating and characterizing individual microphones, microphone arrays, acoustic intensity probes, reference sound power sources, loudspeakers, sirens, and other individual or complex sources of sound.

Semianechoic chambers are built with a hard reflecting floor in order to accommodate heavy machinery or to simulate large factory-floor or outdoor conditions. They can be used in calibrating and characterizing reference sound power sources, obtaining sound power levels of noise sources, and characterizing the sound output of emergency vehicle sirens when mounted on an emergency motor vehicle.

Reverberation chambers are used to perform measurements under conditions approximating those of a diffuse sound field. They can be used in calibrating and characterizing random incidence microphones and reference sound power sources, obtaining sound power ratings of equipment and sound power levels of noise sources, measuring sound absorption coefficients of building materials and panels, and measuring the transmission loss of building partitions and components such as doors and windows.

Prior to using a measurement system to perform absolute measurements of sound, it should be calibrated as a system from microphone, or probe, to indicating device. Acoustic calibrators and piston phones of fixed or variable frequency and amplitude are available for this purpose. These calibrators should be used at a frequency low enough that the pressure, free-field, and random-incidence response characteristics of the measuring microphone(s) are, for practical purposes, equivalent, or at least related in a known quantitative manner for that specific measurement system. In general, the sound pressure produced by these calibrators may vary, depending on the microphone type, whether or not the microphone has a protective grid, atmospheric pressure, temperature, and relative humidity. Correction factors and coefficients are required for conditions of use that differ from those existing during the calibration of the acoustic calibrator or piston phone. For demanding applications, precision sound sources and measuring microphones should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

Vibration Measurement

With the exception of seismic instruments that record or indicate mechanical motion directly via a mechanical or optomechanical mechanism connected to the test surface, vibration measurements involve the use of an electromechanical or interferometric vibration transducer. Here, the term vibration transducer refers to a generic mechanical vibration transducer. Electromechanical and interferometric vibration transducers belong to a large and varied group of transducers that detect mechanical motion and furnish an electrical signal that is quantitatively related to a particular physical characteristic of the motion. The electrical signal may be related to mechanical strain, displacement, velocity, acceleration, or force depending on the design of the transducer. The principles of operation of vibration transducers may involve optical interference; electrodynamic coupling; piezoelectric (including poled ferroelectric) or piezoresistive crystals; or variable capacitance, inductance, reluctance, or resistance. A considerable variety of vibration transducers with a wide range of sensitivities and bandwidths is commercially available. Vibration transducers may be contacting (*e.g.*, seismic transducers) or non-contacting (*e.g.*, interferometric or capacitive). Seismic transducers use a spring mass resonator within the transducer. At frequencies much greater than the fundamental natural frequency of the mechanical resonator, the relative displacement between the

base and the seismic mass of the transducer is nearly proportional to the displacement of the transducer base. At frequencies much lower than the fundamental resonant frequency, the relative displacement between the base and seismic mass of the transducer is nearly proportional to the acceleration of the transducer base. Therefore, seismic displacement and seismic electrodynamic velocity transducers tend to have a relatively compliant suspension with a low resonant frequency; piezoelectric accelerometers and force transducers have a relatively stiff suspension with a high resonant frequency.

Strain transducers include the metallic resistance and the piezoresistive strain gage. For dynamic strain measurements, these are usually of the bonded type, where the gages are bonded directly to the test surface. How accurately a bonded strain gage replicates strain occurring in the test structure is largely a result of how well the strain gage was oriented and bonded to the test surface.

Displacement transducers include the capacitance gage, fringe-counting interferometer, seismic displacement, and linear variable differential transformer (LVDT). Velocity transducers include the reluctance (magnetic) gage, laser Doppler interferometer, and seismic electrodynamic velocity transducer. Accelerometers and force transducers include the piezoelectric, piezoresistive, and force-balance servo.

The sensitivity, frequency limitations, bandwidth, and amplitude linearity of vibration transducers vary greatly with the transduction mechanism and the manner in which the transducer is applied in a given measurement apparatus. The performance of contacting-type transducers can be significantly affected by the mechanical mounting methods and points of attachment of the transducer and connecting cable, and by the mechanical impedance of the structure loading the transducer. Amplitude linearity varies significantly over the operating range of the transducer, with some transducer types or configurations being inherently more linear than others. Other factors that may critically affect the performance or response of a vibration transducer in a given measurement application are temperature; relative humidity; external acoustic, magnetic, and electrostatic fields; transverse vibration; base strain; chemicals; and radiation. A vibration transducer should be selected based on its long- and short-term stability; its performance characteristics (*e.g.*, sensitivity, frequency response, amplitude linearity, self-noise) versus the expected amplitude of vibration, frequency range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations (*e.g.*, size, mass, and resonant frequency).

Vibration exciters, or shakers, are used in structural analysis, vibration analysis of machinery, fatigue testing, mechanical impedance measurements, and vibration calibration systems. Vibration exciters have a table or moving element with a drive mechanism that may be mechanical, electrodynamic, piezoelectric, or hydraulic. They range from relatively small low-power units for calibrating transducers, such as accelerometers, to relatively large high-power units for structural and fatigue testing.

Conditioning amplifiers, power supplies, preamplifiers, charge amplifiers, voltage amplifiers, power amplifiers, filters, controllers, and displays are available as separate components, or as an integral part of a measuring instrument or system, such as a structural analysis system, vibration analyzer, vibration monitoring system, vibration meter, measuring amplifier, multichannel data-acquisition and modal analysis system, or real-time fractional-octave or FFT signal analyzer. Which instrument(s) to include in a vibration measurement system depends on the mechanical quantity to be determined, the purpose of the measurement, and the frequency range and resolution of signal analysis. In the case of vibration measurements, the signal analysis is relatively narrow in bandwidth and may be relatively low in frequency in order to accurately characterize structural resonances. Accelerometers with internal integrated circuitry are available to provide impedance matching or servo control for measuring very low-frequency acceleration (servo accelerometers). Analog and digital integration and differentiation of vibration signals are available through integrating and differentiating networks and amplifiers, and through FFT analyzers, respectively. Vibration measurements made for different purposes (*e.g.*, machinery diagnostics and health monitoring, balancing rotating machinery, analysis of torsional vibration, analysis of machine-tool vibration, modal analysis, analysis of vibration isolation, stress monitoring, industrial control) will generally each dictate different mechanical measurement requirements and a different set of optimal intrumentation.

Because of their inherent long- and short-term stability, amplitude linearity, wide bandwidth, wide dynamic range, low noise, and wide range of sensitivities, seismic accelerometers have traditionally been used as a reference standard for dynamic mechanical measurements. Prior to using a measurement system to perform absolute dynamic measurements of mechanical quantities, it should be calibrated as a system from transducer to indicating device. Calibrated reference vibration exciters, standard reference accelerometers, precision conditioning amplifiers, and precision calibration exciters are available for this purpose. These exciters and standard reference accelerometers can be used to transfer a calibration to another transducer. For demanding applications, a calibrated exciter, or a standard reference accelerometer with connecting cable and conditioning amplifier should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

COMBUSTION ANALYSIS

Two approaches are used to measure the thermal output or capacity of a boiler, furnace, or other fuel-burning device. The direct or calorimetric test measures change in enthalpy or heat content of the fluid, air, or water heated by the device, and multiplies this by the flow rate to arrive at the unit's capacity. The indirect test or flue gas analysis method determines the heat losses in the flue gases and the jacket and deducts them from the heat content (higher heating value) of the measured fuel input to the appliance. A heat balance simultaneously applies both tests to the same device. The indirect test usually indicates the greater capacity, and the difference is credited to radiation from the casing or jacket and unaccounted-for losses.

With small equipment, the expense of the direct test is usually not justified, and the indirect test is used with an arbitrary radiation and unaccounted-for loss factor.

Flue Gas Analysis

The flue gases from burning fossil fuels generally contain CO_2, H_2O, and H_2 with some small amounts of CO, NO_X, SO_X, and unburned hydrocarbons. However, to determine completeness of combustion and efficiency, generally only CO_2 (or O_2) and CO are measured.

In the laboratory, the instruments most commonly used to measure CO and CO_2 are nondispersive infrared (NDIR) analyzers. The NDIR instruments have several advantages: (1) they are not very sensitive to flow rate, (2) no wet chemicals are required, (3) they have a relatively fast response, (4) measurements can be made over a wide range of concentrations, and (5) they are not sensitive to the presence of contaminants in the ambient air.

In the laboratory, oxygen is generally measured with an instrument based on its paramagnetic properties. The paramagnetic instruments are generally used because of their excellent accuracy and because they can be made specific to the measurement of oxygen.

For field testing and burner adjustment, protable combustion testing equipment is available. These instruments generally

measure O_2 and CO with electrochemical cells. The CO_2 is then calculated by an on-board microprocessor and, together with temperature, is used to calculate thermal efficiency. If a less expensive approach is required, a portable orsat system can be used to measure CO_2, and a length-of-stain tube to measure CO.

ROTATIVE SPEED MEASUREMENT

Tachometers

Tachometers, or direct-measuring rpm counters, vary from hand-held mechanical or electric meters to shaft-driven and electronic pulse counters. They are used in general laboratory and shop work to check the rotative speeds of motors, engines, and turbines.

Stroboscopes

Optical rpm counters work by producing a controlled high-speed electronic flashing light. The operator directs the light on a rotating member and increases the rate of flashes-per-minute until the optical effect of stopping rotation of the member is achieved. At this point, the rpm measured is equal to the flashes per minute emitted by the strobe unit. Care must be taken to start at the bottom of the instrument scale and work up, since multiples of the rpm produce almost the same optical effect as true synchronism. Multiples can be indicated by suitable marks positioned on the shaft, such as a bar on one side and a circle on the opposite side. If, for example, the two are seen superimposed, then the strobe light is flashing at an even multiple of the true rpm.

AC Tachometer-Generators

A tachometer-generator consists of a rotor and a stator. The rotor is a permanent magnet driven by the equipment. The stator is a winding with a hole through the center for the rotor. Concentricity is not critical; bearings are not required between rotor and stator. The output can be a single cycle-per-revolution signal whose voltage is a linear function of rotor speed. The polypole configuration that generates 10 cycles per revolution permits measurement of speeds as low as 20 rpm without causing the indicating needle to flutter. The output of the ac tachometer-generator is rectified and connected to a dc voltmeter.

THERMAL COMFORT MEASUREMENT

Thermal comfort depends on the combined influence of clothing, activity, air temperature, air velocity, mean radiant temperature, and air humidity. Thermal comfort is influenced by heating or cooling of particular body parts. This is due to radiant temperature asymmetry (plane radiant temperature), draft (air temperature, air velocity, turbulence), vertical air temperature differences, and floor temperature (surface temperature).

A general description of thermal comfort is given in Chapter 8, and guidelines for an acceptable thermal environment are given in ASHRAE *Standard* 55 (1992b) and ISO 7730 (1984). ASHRAE *Standard* 55 also includes required measuring accuracy. In addition to specified accuracy, ISO 7726 (1985) includes recommended measuring locations and a detailed description of instruments and methods.

Clothing and activity. These are estimated from tables (Chapter 8, ISO/DIS 9920 1990, ISO 8996 1990). The thermal insulation of clothing (clo-value) can be measured on a thermal mannequin (McCullough *et al.* 1985, Olesen 1985). The activity (met-value) can be estimated from measuring CO_2 and O_2 in a person's expired air.

Air temperature. Various types of thermometers may be used to measure air temperature. Placed in a room, the sensor registers a temperature between air temperature and mean radiant temperature. One way of reducing the radiant error is to make the sensor as small as possible, because the convective heat transfer coefficient increases as the size decreases while the radiant heat transfer coefficient is constant. A sensor with a smaller dimension also provides a favorably low time constant. The radiant error can also be reduced by using a shield (an open, polished aluminum cylinder) around the sensor, by using a sensor with a low-emittance surface, or by increasing the air velocity around the sensor artificially (aspirating air through a tube in which the sensor is placed).

Air velocities. In occupied zones, air velocities are usually small (0 to 100 fpm) but have an effect on human thermal sensation. Since the velocity fluctuates, the mean value should be measured over a suitable period, typically 3 min. Velocity fluctuations with frequencies up to 1 Hz significantly increase human discomfort due to draft, which is a function of air temperature, mean air velocity, and turbulence (Chapter 8). The fluctuations can be given as the standard deviation of the air velocity over the measuring period (3 min) or as the turbulence intensity (standard deviation/mean air velocity). Velocity directions may change and are difficult to identify at low air velocities. An omnidirectional sensor with a short response time should be used. A thermal anemometer is suitable. If a hot-wire anemometer is used, the direction of the flow being measured must be perpendicular to the hot wire. Smoke puffs can be used to identify the direction.

Plane radiant temperature. This refers to the uniform temperature of an enclosure in which the radiant flux on one side of a small plane element is the same as in the actual nonuniform environment. It describes the radiation in one direction. The plane radiant temperature can be calculated from the surface temperatures of the environment (half-room) and the angle factors between the surfaces and a plane element (Chapter 8, ASHRAE *Standard* 55-92). The plane radiant temperature may also be measured by a net-radiometer (Chapter 8) or a radiometer with a sensor consisting of a reflective disc (polished) and an absorbent disc (painted black) (Olesen *et al.* 1989).

Mean radiant temperature. This is the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of radiant heat as in the actual nonuniform enclosure. The mean radiant temperature can be calculated from measured surface temperatures and the corresponding angle factors between the person and the surfaces (Chapter 8).

The mean radiant temperature can also be determined from the plane radiant temperature in six opposite directions weighted according to the projected area factors for a person (Chapter 8).

Because of its simplicity, the most commonly used instrument to determine the mean radiant temperature is a black globe thermometer (Vernon 1932, Bedford and Warmer 1935). This thermometer consists of a hollow sphere usually 6 in. in diameter, a flat black paint coating, and a thermocouple or thermometer bulb at its center. The temperature assumed by the globe at equilibrium results from a balance between heat gained or lost by radiation and by convection.

The mean radiant temperatures are calculated from

$$\bar{t}_r = \left[(t_g + 460)^4 + \frac{4.74 \times 10^7 V_a^{0.6}}{\epsilon D^{0.4}} (t_g - t_a) \right]^{1/4} - 460 \quad (21)$$

where

$\bar{t}_r$ = mean radiant temperature, °F
t_g = globe temperature, °F
V_a = air velocity, fpm
t_a = air temperature, °F
D = globe diameter, ft
ϵ = emissivity (0.95 for black globe)

According to Equation (21), air temperature, and air velocity around the globe must also be determined. The globe thermom-

eter is spherical, while mean radiant temperature is defined in relation to the human body. For sedentary people, the globe represents a good approximation. For people who are standing, the globe, in a radiant nonuniform environment, overestimates the radiation from floor or ceiling. An ellipsoid-shaped sensor gives a closer approximation to the human shape. A black globe will also overestimate the influence of short-wave radiation, *e.g.*, sunshine. A flat grey color better represents the radiant characteristic of normal clothing (Olesen 1989). The hollow sphere is usually made of copper, which results in an undesirable high time constant. This can be overcome by using lighter materials, *e.g.*, a thin plastic bubble.

Air Humidity

The water vapor pressure (absolute humidity) is usually uniform in the occupied zone of a space; therefore, it is sufficient to measure absolute humidity at one location. Many of the instruments listed in Table 5 are applicable. At ambient temperatures that provide comfort or slight discomfort, the thermal effect of humidity is only moderate, and highly accurate humidity measurements are unnecessary.

Calculating Thermal Comfort

When the thermal parameters have been measured, their combined effect can be calculated by the thermal indices in Chapter 8. For example, the effective temperature (Gagge *et al.* 1971) can be determined from air temperature and humidity. Based on the four environmental parameters and an estimation of clothing and activity, the predicted mean vote (PMV) can be determined with the aid of tables (Fanger 1982, ISO 1984, Chapter 8). The PMV is an index predicting the average thermal sensation that a group of occupants may experience in a given space.

For certain types of normal activity and clothing, the environmental parameters measured can be compared directly with those described in ASHRAE *Standard* 55 or ISO *Standard* 7730.

Integrating Instruments

Several instruments have been developed to evaluate the combined effect of two or more thermal parameters on human comfort. Madsen (1976) developed an instrument that gives information on the occupants' expected thermal sensation by direct measurement of the PMV value. The comfort meter has a heated ellipsoid-shaped sensor that simulates the body (Figure 22). The estimated clothing (clo), activity in the actual space, and humidity are set on the instrument. The sensor then integrates the thermal effect of the air temperature, mean radiant temperature, and air velocity in approximately the same way the body does. The electronic instrument gives the measured operative and equivalent temperature and calculated PMV and predicted percentage of dissatisfied (PPD).

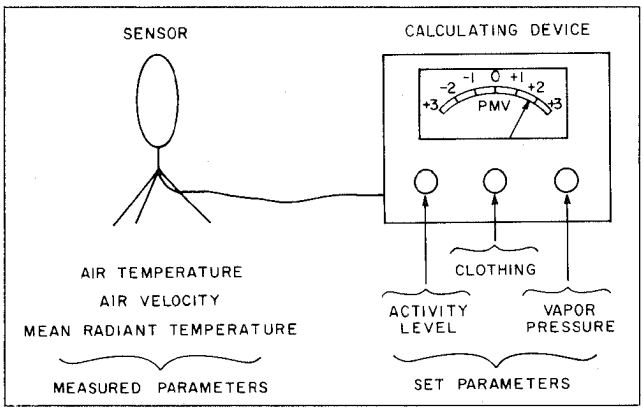

Fig. 22 Madsen's Comfort Meter
(Madsen 1976)

MOISTURE CONTENT AND TRANSFER MEASUREMENT

Little off-the-shelf instrumentation exists to measure the moisture content of porous materials or the moisture transfer through those materials. However, many measurements can be set up with a small investment of time and money. Three moisture properties are most commonly desired—(1) the sorption isotherm, a measure of the amount of water vapor a hygroscopic material will adsorb from humid air; (2) vapor permeability, a measure of the rate at which water vapor will pass through a given material; and (3) liquid diffusivity, a measure of the rate at which liquid water will pass through a porous material.

Sorption Isotherm

A sorption isotherm relates the equilibrium moisture content (EMC) of a hygroscopic material to the ambient relative humidity under conditions of constant temperature. Moisture content is the ratio of the total mass of water in a sample to the dry mass of the sample. Determining a sorption isotherm involves exposing a sample of material to a known relative humidity at a known temperature and then measuring the sample's moisture content after a sufficient period of time for the sample to reach equilibrium with its surroundings. Hysteresis in the sorption behavior of most hygroscopic materials requires that measurements be made both for increasing relative humidity (the adsorption isotherm) and for decreasing relative humidity (the desorption isotherm).

Controlling the ambient relative humidity can be accomplished using saturated salt solutions or mechanical refrigeration equipment (Tveit 1966, Cunningham and Spratt 1984, Carotenulo *et al.* 1991). Precise measurements of the relative humidity produced by various salt solutions have been reported by Greenspan (1977). ASTM *Standard* E104 describes the use of saturated salt solutions (ASTM 1991a). The equilibrium moisture content of a sample is usually determined gravimetrically using a percision balance. The sample dry mass, necessary to calculate moisture content, can be found by oven drying or desiccant drying. Oven dry mass may be less than desiccant dry mass because of the loss of volatiles other than water in the oven (Richards *et al.* 1992).

A major difficulty in the measurement of the sorption isotherms of engineering materials is the long time required for many materials to reach equilibrium—often as long as weeks or months. The rate-limiting mechanism for these measurements is usually the slow process of vapor diffusion into the pores of the material. The use of smaller samples can help reduce the diffusion time.

Vapor Permeability

The diffusive transfer of water vapor through porous materials is often described by a modified form of Fick's law

$$w_v = -\mu\,(dp/dx) \tag{22}$$

where

w_v = mass of vapor diffusing through unit area in unit time
dp/dx = vapor pressure gradient
μ = vapor permeability

In engineering practice, permeance may be used instead of permeability. Permeance is simply permeability divided by the material thickness in the direction of the flow of vapor; thus, while permeability is a material property, permeance depends on thickness.

Measurement of permeability is made with wet cup, dry cup, or modified cup tests. Wet and dry cup tests are described in Chapter 20.

For many engineering materials, vapor permeability is a strong function of mean relative humidity. Wet and dry cups cannot

adequately characterize this dependence on relative humidity. Instead, a modified cup method can be used (McLean *et al.* 1990, Burch *et al.* 1992). The modified cup method replaces the pure water or desiccant within a cup with a saturated salt solution. A second saturated salt solution is used to condition the environment external to the cup. With such an arrangement, the relative humidities on both sides of the sample material can be varied from 0 to 100%. Several cups with a range of mean relative humidities are used to map out the dependence of vapor permeability on relative humidity.

In measuring materials of high permeability, the finite rate of vapor diffusion through air in the cup may become a factor. The air-film resistance could then be a significant fraction of the resistance to vapor flow presented by the sample material. An accurate measurement of high-permeability materials may require an accounting of diffusive rates across all air gaps (Fanney *et al.* 1991).

Liquid Diffusivity

The transfer of liquid water through porous materials may be characterized as a diffusion-like process

$$w_l = -\rho D_l \, d\gamma/dx \qquad (23)$$

where

w_l = mass of liquid transferred through unit area per unit time
ρ = liquid density
$d\gamma/dx$ = moisture content gradient

and where the liquid diffusivity D_l typically shows a strong dependence on moisture content.

Transient measurement methods deduce the functional form of $D_l\gamma$ by observing the evolution of a one-dimensional moisture content profile over time. An initially dry specimen is brought into contact with liquid water. The free water will migrate into the specimen, drawn in by surface tension. The resulting moisture content profile, which changes with time, must be differentiated to find the liquid diffusivity of the material (Bruce and Klute 1956).

Determining the transient moisture content profile typically involves the use of a noninvasive and nondestructive method of measuring local moisture content. Gamma ray absorption (Freitas *et al.* 1991, Kumaran and Bomberg 1985, Quenard and Sallee 1989), X-ray radiography (Ambrose *et al.* 1990), neutron radiography (Prazak *et al.* 1990), and nuclear magnetic resonance (NMR) (Gummerson *et al.* 1979) have all been employed.

Uncertainty in the resulting measurement of the liquid diffusivity is often large because of the necessity to differentiate noisy experimental data.

HEAT TRANSFER THROUGH BUILDING MATERIALS

Thermal Conductivity

The thermal conductivity of a heat insulator, as defined in Chapter 20, is a unit heat transfer factor. Two methods of determining the thermal conductivity of flat insulation are the guarded hot plate and the heat-flowmeter apparatus, according to ASTM *Standards* C 177 and C 518, respectively (ASTM 1985, ASTM 1991b). Both methods use parallel, isothermal plates to induce a steady temperature gradient across the thickness of the specimen(s). The guarded hot plate is considered an absolute method for determining thermal conductivity. The heat-flowmeter apparatus requires calibration, with a specimen having a known thermal conductivity usually determined in the guarded hot plate. The heat-flowmeter apparatus is calibrated by determining the voltage output of its heat flux transducer(s) as a function of the heat flux through the transducer(s).

The basic design of the guarded hot plate consists of an electrically heated plate and two liquid-cooled plates. Two similar specimens of a material are required for a test; one is mounted on each side of the hot plate. A cold plate is then pressed against the outside of each specimen by a clamp screw. The heated plate consists of two sections separated by a small gap. During tests, the central (metering) section and the outer (guard) section are maintained at the same temperature to minimize errors caused by edge effects. The electric energy required to heat the metering section is measured carefully and converted to heat flow. The thermal conductivity of the material can be calculated under steady-state conditions using this heat flow quantity, the area of the metering section, the temperature gradient, and the specimen thickness. The thermal conductivity of cylindrical or pipe insulation (Chapter 20) is determined in a similar manner, but an equivalent thickness must be calculated to account for the cylindrical shape (ASTM 1989b). Transient methods have been developed by D'Eustachio and Schreiner (1952), Hooper and Lepper (1950), and Hooper and Chang (1953) using a line heat source within a slender probe. These instruments are available commercially and have the advantages of rapidity and a small test specimen requirement. The probe is a useful research and development tool, but it has not been as accepted as the guarded hot plate, heat-flowmeter apparatus, or pipe insulation apparatus.

Thermal Conductances and Resistances

Thermal conductances (C-values) and resistances (R-values) of many building assemblies can be calculated from the conductivities and dimensions of their components, as described in Chapter 22. Test values can also be determined experimentally using large specimens representative of the building assemblies tested in the hot box apparatus described in ASTM *Standards* C 236 and C 976 (ASTM 1989c, ASTM 1990a). This laboratory apparatus allows measurement of heat transfer through a specimen under controlled air temperature, air velocity, and radiation conditions. It is specially suited for large nonhomogeneous specimens.

For in-situ measurements, heat flux and temperature transducers are useful in measuring the dynamic or steady-state behavior of opaque building components (ASTM 1991c). A heat flux transducer is simply a differential thermopile within a core or substrate material. There are two types of construction—(1) multiple thermocouple junctions wrapped around a core material, or (2) printed circuits with a uniform array of thermocouple junctions. The transducer is calibrated by determining its voltage output as a function of the heat flux through the transducer. For in-situ measurements, the transducer is installed in either the wall or roof construction, or mounted on an exterior surface with tape or glue. The data obtained from the heat flux and temperature transducers can be used to compute the thermal conductance or resistance of the building component (ASTM 1990b).

AIR INFILTRATION AND AIRTIGHTNESS MEASUREMENT

Two major characteristics describe air infiltration in buildings—air change rates and envelope air leakage. The measurement approaches used to determine these factors are described in Chapter 23. The air change rate of a building refers to the rate at which outdoor air enters the building under normal conditions of weather and ventilation system operation. In general, the air change rate includes both outdoor air taken in through the air-handling system and air leakage through the building envelope (infiltration). The outdoor air intake rate is determined by the design, installation, and operation of the mechanical ventilation system. Infiltration is determined by the extent and distribution of leaks over the building envelope and the pressure differences

across these leaks. These pressure differences are induced by wind, inside-outside temperature differences, and the operation of building mechanical equipment. Building air change rates can only be measured by injecting a tracer gas into a building and monitoring and analyzing the tracer gas concentration response. The instrumentation required for tracer gas testing includes a means of injecting the tracer gas and sampling the air in the building and a tracer gas monitor. There is a variety of tracer gas techniques, distinguished by the injection strategy and analysis approach employed. To fully characterize the air change performance of a building, the air change rate must be measured over a range of weather and equipment operation.

The airtightness of a building envelope can be measured relatively quickly using building pressurization techniques, which are described in Chapter 23. In the pressurization technique, a large fan or blower mounted in a door or window induces a large and roughly uniform pressure difference across the building shell. The airflow required to maintain this pressure difference is then measured. The more leakage in the building, the more airflow is required to induce a specific indoor-outdoor pressure difference. The building airtightness is characterized by the airflow rate at a reference pressure, normalized by the building volume or surface area. Under proper test conditions, the results of a pressurization test are independent of weather conditions. The instrumentation requirements for pressurization testing include air-moving equipment, a device to measure airflow, and a differential pressure gage.

AIR CONTAMINANT MEASUREMENT

Three measures of particulate air contamination include the number, projected area, and mass of particles per unit volume of air (ASTM 1991d, ASTM 1987b, ASHRAE 1971). Each requires an appropriate sampling technique.

Particles are counted by capturing them in impinges, impactors, membrane filters, and thermal or electrostatic precipitators. Counting is done by microscope, using stagecounts if the sample covers a broad range of sizes.

Electronic particle counters give rapid data of particle size distribution and concentration depending on the design of the instrument. However, their accuracy depends on careful calibration, appropriate maintenance, and proper application. Particle counters have been used in indoor office environments as well as clean rooms.

Projected area determinations are usually made by sampling onto a filter paper and comparing the light transmitted or scattered by this filter to a standard filter. The staining ability of dusts depends on the projected area and refractive index per unit volume. For sampling, filters must collect the minimum size particle of interest. In this respect, membrane or glass fiber filters are recommended.

To determine particle mass, a measured quantity of air is drawn through filters, preferably of membrane or glass fiber, and the filter mass is compared to the mass before sampling. Electrostatic or thermal precipitators and various impactors have also been used. For further information, see ACGIH (1983), Lundgren *et al.* (1979), and Lodge (1989).

Chapter 40 of the 1991 ASHRAE *Handbook—Applications* presents information on measuring and monitoring gaseous contaminants. Relatively costly analytical equipment, which must be calibrated and operated carefully by experienced personnel, is needed. Numerous methods of sampling the contaminants as well as the laboratory analysis techniques used after sampling are specified. Some of the analytical methods are specific to a single pollutant; others are capable of presenting a concentration spectrum for many compounds simultaneously.

LIGHTING MEASUREMENT

Light level, or illuminance, is usually measured with a photocell made from a semiconductor such as silicon or selenium. Such photocells produce an output current proportional to incident luminous flux, and when linked with a microammeter, color- and cosine-corrected filters and multirange switches are used in inexpensive hand-held light meters and more precise instruments. Different cell heads allow multirange use in precision meters.

Cadmium sulfide photocells, in which the resistance varies with illumination, are also used in light meters. Both gas-filled and vacuum photoelectric cells are in use.

Small survey-type meters are not as accurate as laboratory meters; their readings should be considered approximate, although consistent, for a given condition. Their range is usually from 5 to 5000 footcandles. Precision low-level meters have cell heads with ranges down to 0 to 2 footcandles.

A photometer installed in a revolving head is called a goniophotometer and is used to measure the distribution of light sources or luminaires. To measure total luminous flux, the luminaire is placed in the center of a sphere painted inside with a high-reflectance white with a near perfect diffusing matte surface. Total light output is measured through a small baffled window in the sphere wall.

To measure irradiation from germicidal lamps, a filter of fused quartz with fluorescent phosphor is placed over the light meter cell.

If meters are used to measure the number of lumens per unit area diffusely leaving a surface, luminance (cd/in^2) instead of illumination (footcandles) is read. Light meters can be used to measure luminance; or electronic lux meters containing a photo tube, amplifier, and microammeter can read luminance directly. In the case of a perfectly diffuse reflecting surface, which has a constant luminance regardless of viewing angle, the unit of footlamberts in $lumens/ft^2$ is sometimes applied.

DATA RECORDING

The trend toward computer entry and processing of data, greater automation, and improved data accuracy have led to the pervasive use of digital data acquisition systems for dynamic as well as static data. Almost every type of transducer and sensor is available with the necessary interface system to make it computer compatible. The transducer itself begins to lose its identity when integrated into a system that incorporates such features as linearization, offset correction, self-calibration, and so forth. This trend has eliminated the concern regarding the details of signal conditioning and amplification of basic transducer outputs. The personal computer is integrated into every aspect of data recording, including sophisticated graphics, acquisition and control, and analysis.

The event duration for a specific test may last from microseconds to years. For short-term transient testing, data are often recorded on analog tape or stored in a digital memory for subsequent playback, processing, and display. Long-term data are usually recorded on digital cassette tapes at timed intervals and collected on a periodic (*e.g.*, quarterly) basis for processing. Between these two extremes, the more typical application involves real-time monitoring and quick-look display of events lasting up to an hour, with off-line processing and analysis performed as needed.

Other means of recording, such as chart recorders, which can either be multipurpose or specifically designed for a given sensor, are available. Chart recorders provide a visual indication and a hard copy record of the data. Rarely is the output of a chart

recorder used to process data. Simple indicators and readouts are used mostly to monitor the output of a sensor visually. In most situations, analog indicators such as d'Arsonval movement meters have been rendered obsolete by modern digital indicators. Industrial environments commonly employ signal transmitters for control or computer data-handling systems to convert the signal output of the primary sensor into a compatible common signal span, for example, the standard 4-20 mA current loop. All signal conditioning (ranging, zero suppression, reference-junction compensation) is provided at the transmitter. Thus, all recorders and controllers in the system can have an identical electrical span, with variations only in charts and scales offering the advantages of interchangeability and economy in equipment cost. Long signal transmission lines can be used, and receiving devices can be added to the loop without degrading performance.

The vast selection of available hardware, an often confusing set of terminology, and the challenge of optimizing the performance/cost ratio for a specific application makes the task of configuring a data acquisition system difficult. Two major factors influence the selection of recording systems—(1) the need for a number of measurements of the desired parameters, and (2) the need for acquired data to be processed. A system specifically configured to meet a particular measurement need can quickly become obsolete if it has inadequate flexibility. Other considerations, such as thermal, mechanical, electromagnetic interference, portability, and meteorological factors, also influence the selection of the recording system.

Digital Recording

A digital data acquisition system must contain an interface, *i.e.*, a system involving one or several analog-to-digital converters, and in the case of multichannel inputs, circuitry for multiplexing. The interface may also provide excitation for transducers, calibration, and conversion of units. The digital data are arranged into one or several standard digital bus formats. Many data acquisition systems are designed to acquire data rapidly and store large records of data for later recording and analysis. Once the input signals have been digitized, the digital data is essentially immune from noise and can be transmitted over great distances.

Information is transferred to a computer/recorder from the interface as a pulse train, which can be transmitted as 4-, 8-, 12-, 16-, or 32-bit words. An 8-bit word or byte and many communications methods are rated according to their bytes per second transfer rate. Digital data is transferred in either a serial or parallel mode. Serial transmission means that the data is sent as a series of pulses, one bit at a time. Although slower than a parallel system, serial interfaces require only two wires, which lowers their cabling cost. The speed of serial transmissions are rated according to their symbols/second rate, or baud rate. In parallel transmission, the entire data word is transmitted at one time. To do this, each bit of a data word has to have its own transmission line; other lines are needed for clocking and control. Parallel transmission is used for short distances or when high data rates are required. Serial transmission must be used for long-distance communications where wiring costs are prohibitive.

The two most popular interface bus standards currently used for data transmission are the IEEE 488 or the GPIB (general purpose interface bus) and the RS232 serial interface. The IEEE 488 bus system feeds data down 8 parallel wires, one 8-bit data byte at a time. This parallel operation allows it to transfer data rapidly with up to 1-million characters per second. However, the IEEE 488 bus is limited to a cable length of 65 ft and requires an interface connection on every meter for proper termination. The RS232 system feeds data serially down two wires, one bit at a time. The RS232 system can operate up to 9600 baud, which amounts to only 1200 8-bit bytes per second. An RS232 line may be over 1000 ft long. For longer distances, it may feed a modem to send data over standard telephone lines. A local area network (LAN) may be available in a facility for transmitting information. With appropriate interfacing, transducer data is available to any computer connected to the network.

Bus measurements can greatly simplify three basic applications—data gathering, automated limit testing, and computer-controlled processes. In data gathering applications, readings are collected over time. The most common applications include aging tests in quality control, temperature tests in quality assurance, and testing for intermittents in service. A controller can monitor any output indefinitely and then display the data directly on its screen or record it on magnetic tape or disks for future use.

In automated limit testing, the computer simply compares each measurement with limits programmed ahead of time. The controller converts the readings to a good/bad readout. Automatic limit testing becomes highly cost-effective when working with large number of parameters of a particular unit under test.

In computer-controlled processes, the IEEE 488 bus system becomes a permanent part of a larger, completely automated system. For example, a large industrial process may require many electrical sensors that feed a central computer controlling many parts of the manufacturing process. For example, an IEEE 488 bus controller collects readings from several sensors and saves the data until asked to dump an entire batch of readings to a larger central computer at one time. Used in this manner, the IEEE 488 bus controller serves as a slave of the central processor unit.

Dynamic range and accuracy are two important parameters that must be considered in a digital recording system. *Dynamic range* refers to the ratio of the maximum input signal for which the system is useful to the noise floor of the system. The *accuracy* figure for a system is impacted by the noise floor, nonlinearity, temperature, time, crosstalk, and so forth. In selecting an 8-, 10-, or 12-bit analog-to-digital converter, the designer cannot assume that the system accuracy will necessarily be determined by the resolution of the encoders, *i.e.*, 0.4%, 0.1%, and 0.25%, respectively. If the sensor preceding the converter is limited to 1% full-scale accuracy, for example, no significant benefits are gained by using a 10- or 12-bit system over an 8-bit system and suppressing the least significant bit. However, a greater number of bits may be required to cover a larger dynamic range.

Chart Recorders

Chart recorders convert electrical signals (analog or digital) to records of the data against time on a hard copy, usually paper. Mechanical styluses use ink, hot wire, pressure, or electrically sensitive paper to provide a continuous trace. They are useful up to a few hundred hertz. Thermal and ink recorders are confined to chart speeds of a few inches per second for recording relatively slow processes. Newer advances in portable recorders provide multichannel inputs and up to 25 kHz real time frequency response without using a pen or pen motor. XY recorders and plotters allow two variables to be recorded with respect to one another. Their response times are generally limited to that of thermal and ink recorders. Oscillographic recorders have largely been made obsolete by digital oscilloscopes.

Tape Recorders

A tape recorder records and reproduces information tape coated with a magnetizable material. Tapes can be of the open-reel type, which permit long-time recordings and multichannel data recording; or tapes can be housed in compact cassettes, which enhances portability. A number of information channels are usually recorded side by side on tape, *e.g.*, 7 on 0.5-in. tape or 14 on 1-in. tape. Instrumentation tape recorders are classified into three general types that refer to the coding method of the signal—direct or analog recording, FM recording, and digital or pulse code modulation.

Direct recording tape recorders, similar to general-purpose audio tape recorders, generally have a frequency response from 4 Hz at a tape speed of 1.5 in/s and up to about 60 kHz at 15 in/s. Their reproduction accuracy is about ±5%, and their dynamic range is limited, unless a compressor/expander (compander) unit is employed which can increase the dynamic range to about 70 dB. The main virtue of direct recorders is their low cost.

Frequency modulation (FM) instrumentation recorders convert the input signal proportional to frequency. Their main advantage is that signal frequencies down to dc can be recorded. Their upper frequency response is about 20 kHz at 15 in/s. Both the FM and direct-type recorders have a signal to noise ratio of about 40 dB; FM recorders are accurate to about ±1%.

Digital tape recorders, sometimes referred to as rotary storage recorders (RSR) or rotary digital audio tape (R-DAT) recorders, are the newest recording devices in the field of magnetic tape recording. The term rotary refers to the rotating recording head, which increases the head-to-tape speed. (Greater bandwidth is achieved in any recorder by increasing head-to-tape speed.) Usually, the rotating head is arranged to create a helical scan. Thus, while a longitudinal recording has continuously recorded signals on tracks running the length of the tape, each swipe on a helical scan recording provides discrete blocks of recorded signal.

A digital tape recorder first requires an analog-to-digital conversion of the signal. The resultant bit stream of binary numbers, pulse code modulation (PCM), are, in turn, recorded on the tape in terms of high and low values (saturated positive and negative magnetizations). During playback, the pulse train that is first read and then reconstructed permits the signal's sequence of binary numbers to be reconstituted. This, in turn, leads to the reconstruction of an analog signal after an appropriate digital-to-analog conversion. Most digital tape recorders have standard interfaces allowing data transfer directly to other equipment, such as computers.

An R-DAT recorder has a bandwidth comparable to direct or FM recording, but the most common recorders have a sampling frequency of 48 kHz giving a frequency response of 20 kHz. Multiple recording channels are usually available, but the frequency response drops proportionally to the number of channels. However, their main feature is superior signal-to-noise ratio and dynamic range, which is at least 70 dB. Typical data quantization levels are 14 to 16 bits with error correction codes.

Wind Effects on System Operation 14.8
Building Internal Pressure and Flow Control 14.9
Atmospheric Dispersion of Building Exhaust 14.9
Estimating Intake Contamination 14.10
Exhaust Stack Design 14.11
Heat Rejection Equipment 14.15
Scale Model Simulation and Testing 14.15
Symbols 14.16

AIRFLOW around buildings affects worker safety, process and building equipment operation, weather and pollution protection at inlets, and the ability to control environmental factors of temperature, humidity, air motion, and contaminants. Wind causes surface pressures that vary around buildings, changing intake and exhaust system flow rates, natural ventilation, infiltration and exfiltration, and interior pressure. The mean flow patterns and turbulence of wind passing over a building can cause a recirculation of exhaust gases to air intakes. This chapter contains information for evaluating flow patterns, estimating wind pressures and air intake contamination, and solving problems caused by the effects of wind on intakes, exhausts, and equipment. Related information can be found in Chapters 11, 13, 23, and 24 of this volume; in Chapters 25, 27, and 47 of the 1991 Applications volume; and in Chapters 26, 31, 36, and 37 of the 1992 Systems and Equipment volume.

FLOW PATTERNS

Buildings of an even moderately complex shape, such as L- or U-shaped structures formed by two or three rectangular blocks, can generate flow patterns too complex to generalize for design. To determine flow conditions influenced by surrounding buildings or topography, a wind tunnel or water channel test of scale models or tests of existing buildings are required. However, if a building is oriented perpendicular to the wind, it can be considered as consisting of several independent rectangular blocks. Only isolated rectangular block buildings will be discussed here. Hosker (1984, 1985) reviews the effects of nearby buildings.

The mean speed of wind approaching a building increases with height above the ground (Figure 1). Both the upwind velocity profile shape and its turbulence level strongly influence flow patterns and surface pressures. A stagnation zone exists on the upwind wall. The flow separates at the sharp edges to generate recirculating flow zones that cover the downwind surfaces of the building (roof, sides, and leeward walls) and extend for some distance into the wake. If the building has sufficient length L in the windward direction, the flow will reattach to the building (Figure 2) and may generate two distinct regions of separated recirculating flow—on the building and in its wake.

Surface flow patterns on the upwind wall are largely influenced by approach wind characteristics. Higher wind speed at roof level causes a larger stagnation pressure on the upper part of the wall than near the ground, which leads to downwash on the lower one-half to two-thirds of the building (Figure 1). On the upper one-quarter to one-third of the building, the surface flow is directed upward over the roof. For a building whose height H is three or more times the width W of the upwind face, an intermediate zone can exist between the upwash and downwash regions, where the surface streamlines pass horizontally around the building. The downwash on the lower surface of the upwind face separates from the building before it reaches ground level and moves upwind to form a vortex that can generate high velocities close to the ground. This ground level upwind vortex is carried around the sides of the building in a U shape (Figure 1b) and is responsible for the suspension of dust and debris that can contaminate air intakes close to ground level.

Recirculation and High Turbulence Regions

For wind perpendicular to a building wall, the height H and width W of the upwind building face determine the flow patterns shown in Figure 3. According to Wilson (1979), the scaling length R which combines these dimensions is:

$$R = B_s^{0.67} B_L^{0.33} \quad (1)$$

where B_s is the smaller and B_L the larger of the dimensions H and W. When B_L is larger than $8B_s$, use $B_L = 8B_s$ in Equation (1). For buildings with varying roof levels or with wings separated by at least a distance B_s, only the height and width of the building face below the portion of the roof in question should be used to calculate R. Wilson (1976) indicates that for a flat-roofed building, the recirculation region maximum height H_c, at location X_c, and reattachment lengths L_c and L_r shown in Figures 3 and 17 are:

$$H_c = 0.22R \quad (2)$$
$$X_c = 0.5R \quad (3)$$
$$L_c = 0.9R \quad (4)$$
$$L_r = 1.0R \quad (5)$$

The downwind boundary of the rooftop recirculation region may be approximated by a straight line sloping downward from H_c to the roof at L_c. The dimensions of the recirculation zones are somewhat sensitive to the intensity and scale of turbulence in the approaching wind. High levels of turbulence from upwind obstacles may decrease the coefficients in Equations (2) through (5) by up to a factor of 2. Turbulence in the recirculation region and in the approaching wind also causes the reattachment locations on Figure 2 to fluctuate.

To account for changes in roof level, penthouses, and equipment housings and enclosures, the scaling length R of each of these obstacles should be calculated from Equation (1) using the dimensions of the upwind face of the obstacle. The recirculation region for each obstacle may be calculated from Equations (2), (3), and (4). The length L_r of the recirculation region downwind from the obstacle, or from the entire building, is given by Equation (5), with R based on the dimensions of the downwind face of the obstacle. The high turbulence region boundary Z_2 in Figure 17 follows a 1:10 (5.7°) downward slope from the top of the recirculation regions at X_c or L_r. When an obstacle is close to the

The preparation of this chapter is assigned to TC 2.5, Air Flow Around Buildings

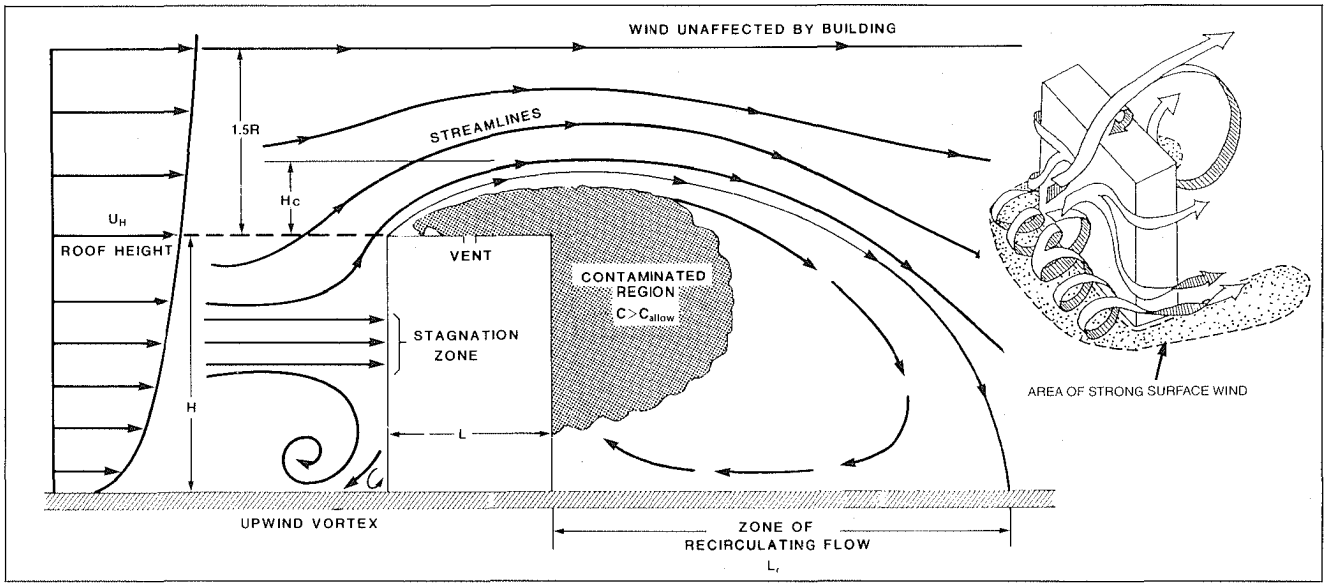

Fig. 1 Flow Patterns around Rectangular Building

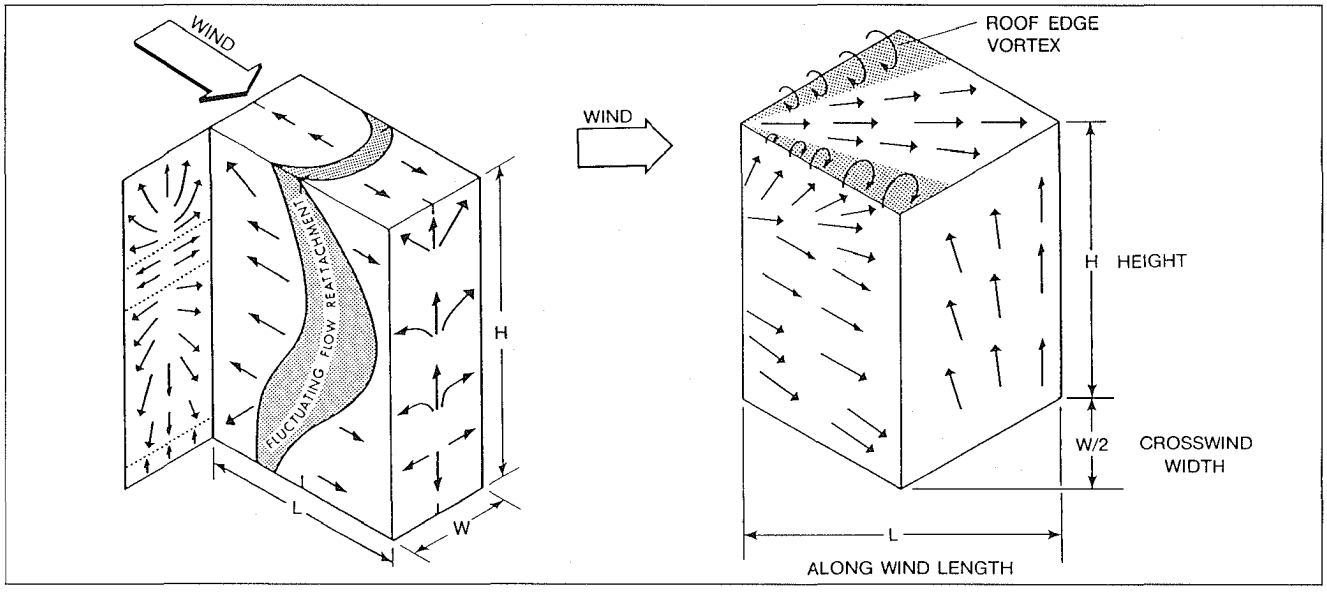

Fig. 2 Surface Flow Patterns and Building Dimensions

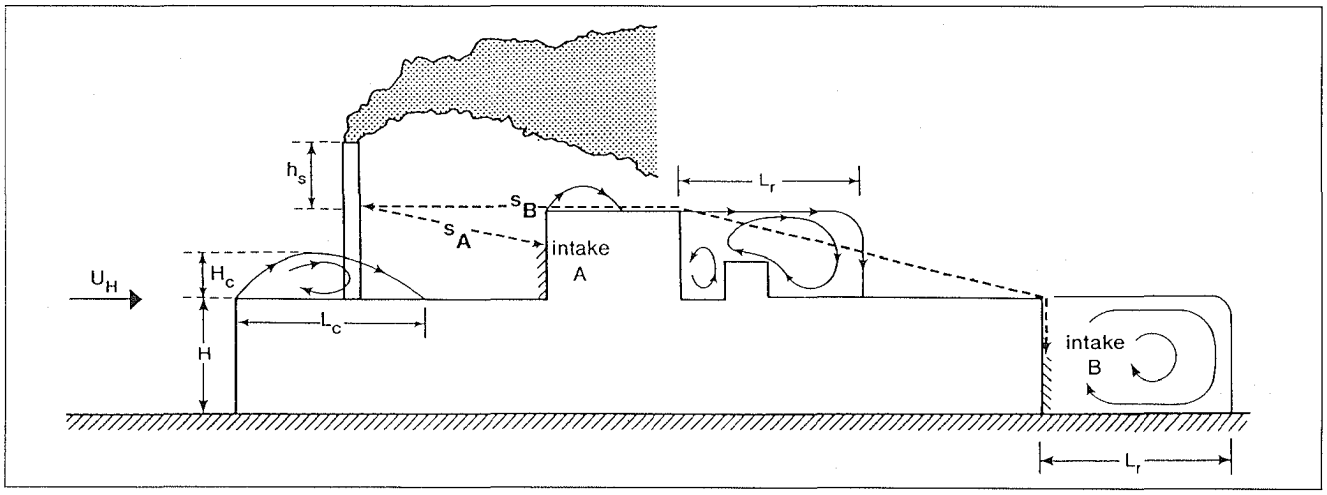

Fig. 3 Flow Recirculation Regions and Exhaust to Intake Stretched String Distances (Wilson 1982)

upwind edge of a roof or near another obstacle, the flow recirculation zones interact. Wilson (1976) gives methods of dealing with these situations.

Building-generated turbulence is confined to the roof wake region, whose upper boundary Z_3 in Figure 17, is given by

$$Z_3/R = 0.28(X/R)^{0.33} \quad (6)$$

where X is the distance from the upwind roof edge where the recirculation region forms. Building-generated turbulence decreases with height above roof level. At the edge of the rooftop wake boundary Z_3, the turbulence intensity is close to the background level in the approach wind. High levels of turbulence exist below the boundary Z_2 (Figure 17).

Streamline patterns are independent of wind speed and depend mainly on building shape and upwind conditions. Because of the three-dimensional flow around a building, the shape and size of the recirculation airflow is not constant over the surface; instead, it reattaches closer to the upwind face of the building along the edges at the roof and at ground level (Figure 2). The height of the recirculation region also decreases near roof edges.

The wind above the roof recirculation region is affected by the presence of the building; the flow accelerates as the streamlines curve upward over the roof and decelerates as they curve downward into the wake on the lee side of the building. The distance above roof level where a building influences the flow is approximately $1.5R$ (Figure 1). The roof pitch begins to affect flow when it exceeds about 15° (1:4). When roof pitch reaches 20° (1:3), the flow remains attached to the upwind pitched roof and produces a recirculation region downwind from the roof ridge that is larger than that for a flat roof. The extent of these flow recirculation zones can be estimated by using the roof ridge height for the dimension H in Equations (1) to (5).

The downwind wall of a building faces a region of low average velocity and high turbulence. Velocities near this wall are typically one-quarter of those at the corresponding upwind wall location. Figures 1 and 2 show that an upward flow exists over most of the downwind walls. A flow recirculation region extends for an approximate distance $L_r = 1.0R$ downwind.

If the angle of the approach wind is not perpendicular to the upwind face, complex flow patterns result. Strong vortices develop from the upwind edges of a roof, causing a strong downwash into the building wake above the roof. High speeds in these vortices cause large negative pressures near roof corners that can be a hazard to roof-mounted equipment during high winds. When the angle between the wind direction and the upwind face of the building is less than about 70°, the downwash-upwash patterns on the upwind face of the building are less pronounced, as is the ground level vortex. For an approach flow angle of 45°, streamlines remain close to the horizontal in their passage around the sides of the building (Figures 1 and 2), except near roof level where the flow is sucked upward into the roof edge vortices.

WIND PRESSURES ON BUILDINGS

In addition to the flow patterns described previously, the turbulence or gustiness of the approaching wind and the unsteady character of the separated flows cause surface pressures to fluctuate. The pressures discussed here are time-averaged values, with an averaging period of about 600 s. Instantaneous pressures may vary significantly above and below these averages, and peak pressures two or three times the mean values are possible. While peak pressures are important with regard to structural loads, mean values are more appropriate for computing infiltration and ventilation rates. The time-averaged surface pressures are proportional to the wind velocity pressure p_v in lb/ft² given by Bernoulli's equation

$$p_v = \rho U_H^2/2_g \quad (7)$$

where U_H is the approach wind speed (fps) at upwind wall height (Figures 1 and 17), and ρ is the outdoor air density (lb/ft³). The difference p_s between the pressure on the building surface and the local outdoor atmospheric pressure at the same level in an undisturbed wind approaching the building is given by

$$p_s = C_p p_v \quad (8)$$

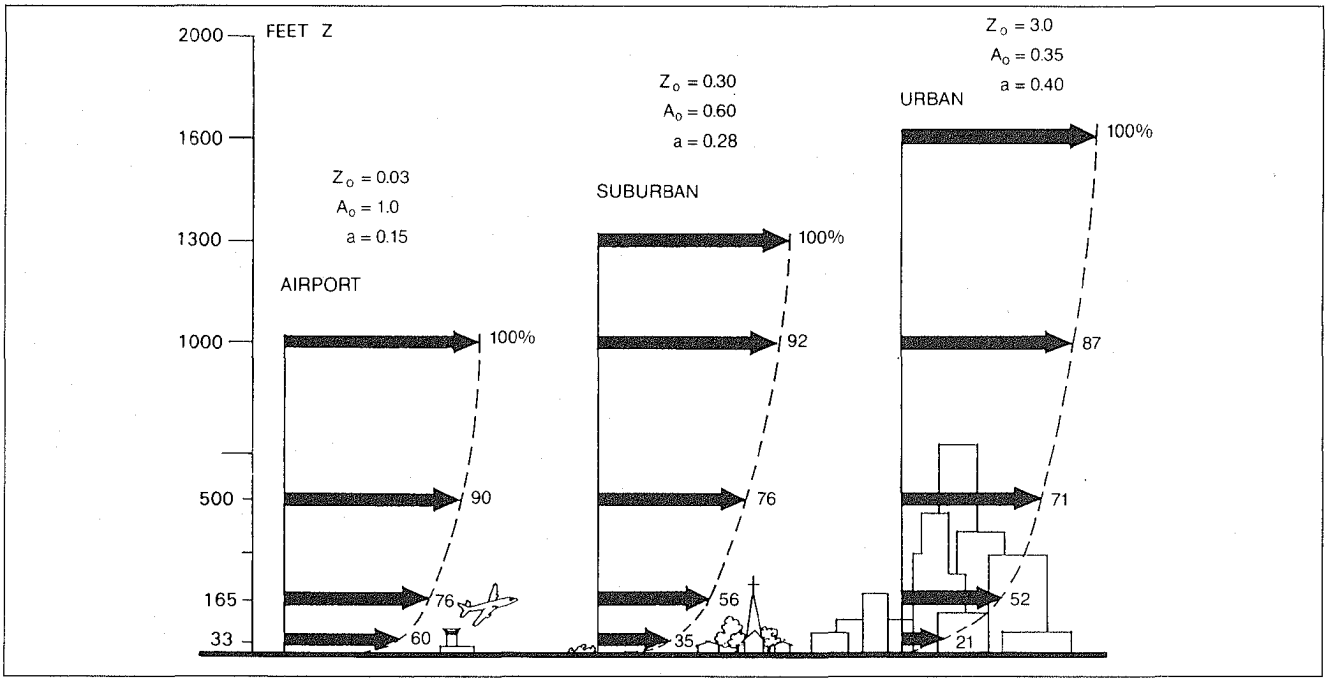

Fig. 4 Typical Mean Wind Speed Profiles over Different Terrain Roughness

The local wind speed U_H at the top of the wall required for Equation (7) is estimated by applying terrain and height corrections to the speed U_{met} from a nearby meteorological station. The wind speed U_{met} from airport meteorological stations is measured at a height H_{ref}, usually about 33 ft, in open flat terrain. U_{met} is related to the reference wind speed U_{ref} at the same height in the local building terrain by

$$U_{ref} = A_o U_{met} \tag{9}$$

where the constant A_o in Figure 4 depends on the local terrain roughness. Figure 1 shows that the wind speed U_H at wall height depends on the velocity profile in the approach wind. Thus:

$$U_H = U_{ref}(H/H_{ref})^a \tag{10}$$

where a is the velocity profile exponent given in Figure 4. The scaling length Z_o for terrain roughness in Figure 4 is based on an alternate logarithmic variation of wind speed with height. Values of Z_o are typically 5 to 10% of the average height of the small-scale terrain roughness features, such as buildings, obstacles, trees, and other vegetation. This average roughness height includes roughness features for a distance of about 3 mi upwind of the site. Equation (10) gives the wind speed at height H above the plan area-weighted average height of local obstacles, such as buildings and vegetation. At heights at or below this average obstacle height, *e.g.*, at roof height in densely built-up suburbs, the speed depends on the geometrical arrangement of the buildings, and Equations (9) and (10) are less reliable.

Local Wind Pressure Coefficients

Values of the pressure coefficient C_p depend on building shape, wind direction, and the influence of nearby buildings, vegetation, and terrain features. Accurate determination of C_p can be obtained only from wind tunnel model tests of the specific site and building. Ventilation rate calculations for single, unshielded rectangular buildings can be reasonably estimated using existing wind tunnel data.

Figure 5 shows wall pressure coefficients on a tall building with a square cross section for simulated urban terrain (Davenport and Hui 1982), and Figure 6 for a low-rise building (Holmes 1986). Generally, high-rise buildings are those where the height H is more than three times the crosswind width W. For $H > 3W$, use Figure 5, and for $H < W$, use Figure 6. At a wind angle $\theta = 0°$, with the wind perpendicular to the face in question, the pressure coefficients are positive, and the magnitude reduces near the sides and the top as the flow velocities increase near the edges. There is a general increase of C_p with height, which reflects the increasing velocity pressure in the approach flow. As the wind direction moves off normal, the region of maximum pressure occurs closer to the upwind edge of the building. At a wind angle of 45°, the pressures become negative at the downwind edge of the front face; at some angle between $\theta = 60°$ and $\theta = 75°$, they become negative over the whole face. Maximum suction (negative) pressure occurs near the upwind edge of the side and for $\theta = 90°$, the pressures then recover towards zero away from the leading edge. The degree of this recovery depends on the length of the side in relation to the width of the structure. For wind angles larger than 100°, the side is completely within the separated flow of the wake, and the spatial variations in pressure over the face are not as great. The average pressure on a face is above zero for wind angles from 0 to

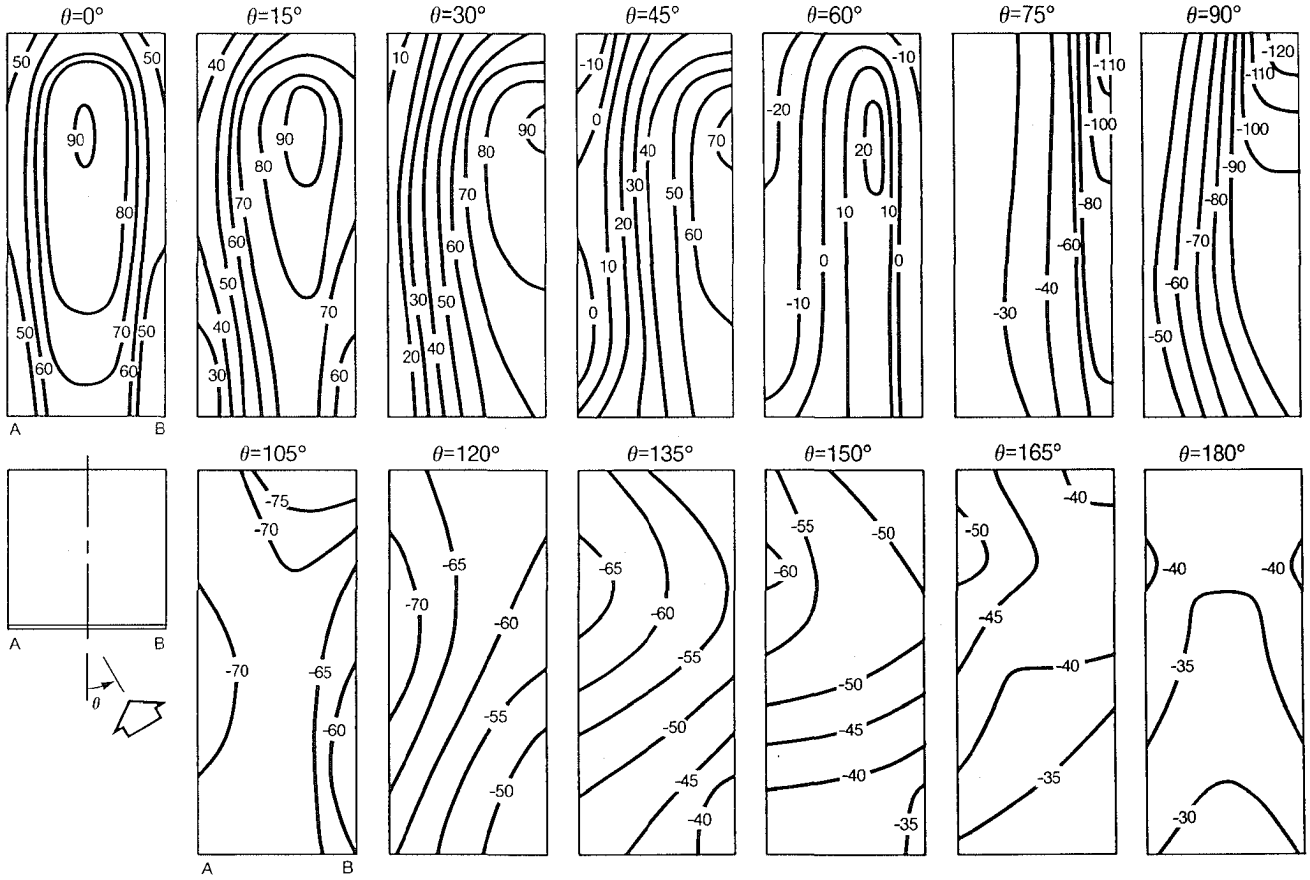

Fig. 5 Mean Pressure Coefficients ($C_p \times 100$) on Tall Building for Varying Wind Direction
(Davenport and Hui 1982)

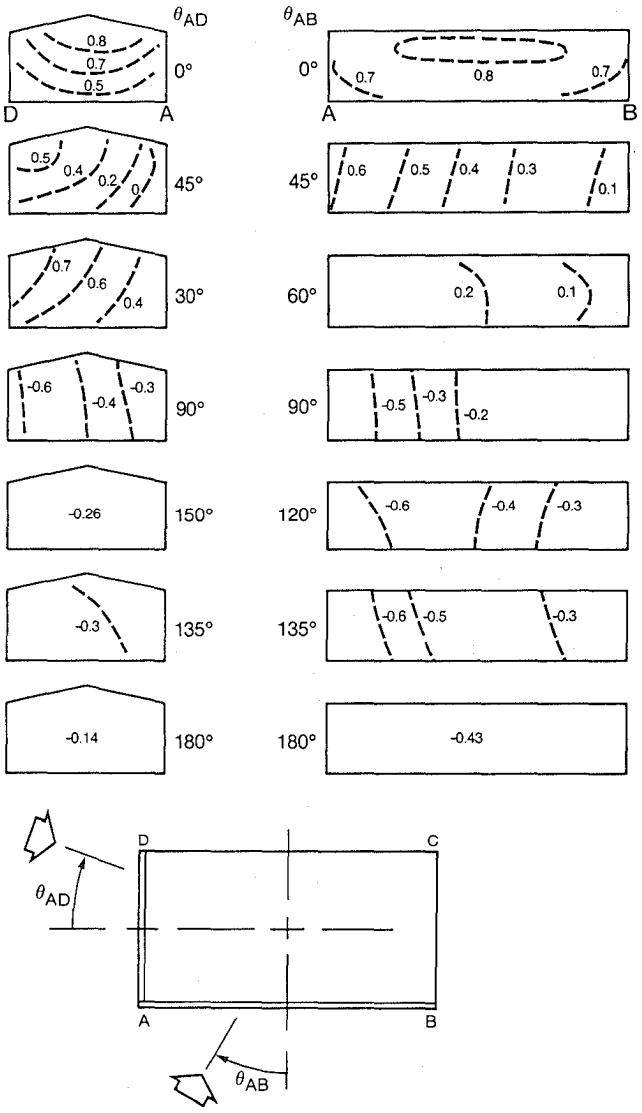

Fig. 6 Mean Pressure Coefficients on Walls of Low-Rise Building
(Holmes 1986)

about 60° and below zero for 60 to 180°. A similar pattern of behavior in the wall pressure coefficients for the low-rise building is shown in Figure 6. Here the recovery from the strong suction with distance from the upwind edge is more rapid.

Surface Averaged Wall Pressures

Figure 7 shows the surface pressure coefficient averaged over a complete wall C_s of a low-rise building (Swami and Chandra 1987). The figure also includes the values calculated from the pressure distributions shown in Figure 6. Similar results for a tall building are shown in Figure 8 (Akins *et al.* 1979).

The wind-induced indoor-outdoor pressure difference is found using the coefficient $C_{p(in\text{-}out)}$ which is

$$C_{p(in\text{-}out)} = C_p - C_{in} \tag{11}$$

The mean of the spatially averaged wall pressure coefficients C_s in Figures 7 and 8 for the four building walls is about −0.2 for most wind directions. This implies that for uniformly distributed air leakage sites in all the walls, the internal wind-induced pressure coefficient will be about $C_{in} = -0.2$. Chapter 22 explains how stack effect pressures induced by the indoor-outdoor temperature difference combine with wind-induced pressures.

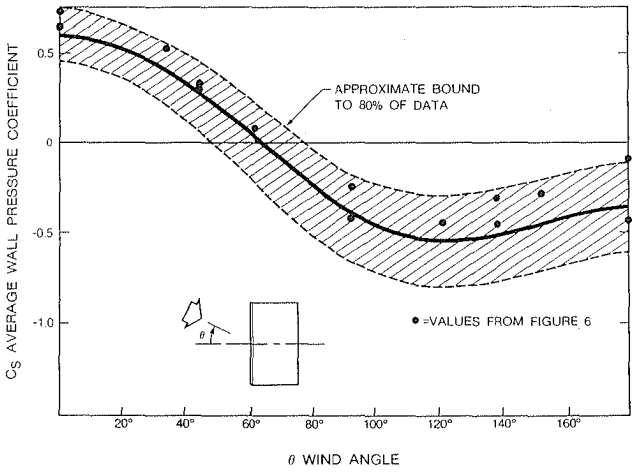

Fig. 7 Variation of Wall Averaged Pressure Coefficients for Low-Rise Building
(Swami and Chandra 1987)

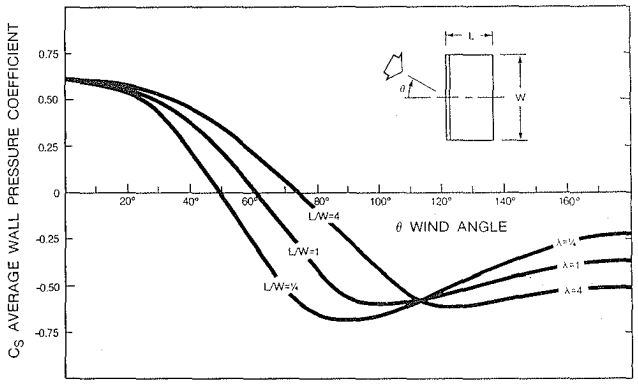

Fig. 8 Wall Averaged Pressure Coefficients for Tall Building, $\lambda = L/W$

Roof Pressures

Surface pressures on the roof of a low-rise building depend strongly on roof slope. Figure 9 shows typical distributions for a wind direction normal to a side of the building. For very low slopes, the pressures are negative over the whole roof surface. The magnitude is greatest within the separated flow zone near the leading edge and recovers toward the free stream pressure away from the edge. For steeper slopes, the pressures are weakly positive on the windward slope and negative within the separated flow over the leeward slope. With a wind angle of about 45°, the vortices originating at the leading corner of a roof with a low slope can induce very large localized negative pressures. Figure 10 shows the average pressure coefficient over the roof of a tall building (Akins *et al.* 1979).

Interference and Shielding Effects on Pressures

Nearby structures strongly influence surface pressures on both high- and low-rise buildings. These effects are very strong for spacing to height ratios less than five, where the distributions of pressure shown in Figures 6 through 9 do not apply. While the effect of shielding is still significant at larger spacings, for low-rise buildings it is largely accounted for by the reduction in P_v with the increased terrain roughness shown in Figure 4 and defined in Equation (7). Chapter 23 gives shielding coefficients for air infiltration and ventilation applications.

(Holmes 1986)

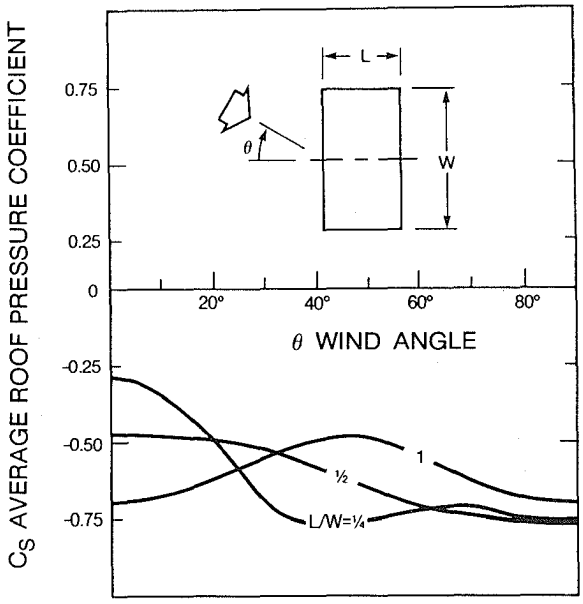

Fig. 10 Averaged Roof Pressure Coefficients for Tall Building

Sources of Wind Data

To design for the effects of airflow around buildings, wind speed and direction frequency data must be obtained. These data provide the number of calms and occurrences of wind speeds within several wind speed intervals, for each of 16 wind directions. Frequency data for mean hourly wind speeds nominally at 30 ft above ground level can be found in a summarized printed pamphlet form or in full digital records on magnetic tape for 1945 through 1985 from the National Climatic Center in Asheville, North Carolina, for numerous sites within the United States and worldwide, and from the Atmospheric Environment Service in Downsview, Ontario, for Canadian sites. ASHRAE (1986) also has limited wind frequency data available for microcomputers.

Using a single prevailing wind direction for design may cause serious errors. For any set of wind direction frequencies, one direction will always have a somewhat higher frequency of occurrence. Thus, it is often called the prevailing wind, even when winds from different directions may be almost as frequent.

Winds aloft data measured at heights of 1300 ft and higher above ground level can also be obtained from the National Climatic Center for fewer sites. These data are often used in boundary layer wind tunnel studies to relate actual wind probabilities to the velocities measured around model buildings. The mean wind speeds aloft are not influenced by individual obstructions at ground level and are more representative of a larger region around a meteorological station. The variation of wind speed with height causes wind changes from those associated with winds aloft to those at ground level. These anticlockwise (*e.g.*, north toward northwest) directional changes are up to 30° in the roughest urban terrain and 15° in smooth terrain.

When using long-term meteorological records, check the history of mounting conditions for the anemometer, because the instrument may have been relocated and its height varied. This can affect its directional exposure and recorded wind speed. Equation (10) can be used to correct wind data collected at different mounting heights. Poor anemometer exposure due to obstructions or mounting on top of a building cannot be easily corrected, and the records for that period should be deleted.

If an estimate of the probability of an extreme wind speed outside the range of the recorded values at a site is required, the observations may be fitted to an appropriate probability distribution and particular probabilities calculated from the fitted curve function, as in Figure 11. This process is usually repeated for each of the 16 wind directions. Where estimates of extreme probabilities are required, curve fitting at the tail of the distribution is extremely important.

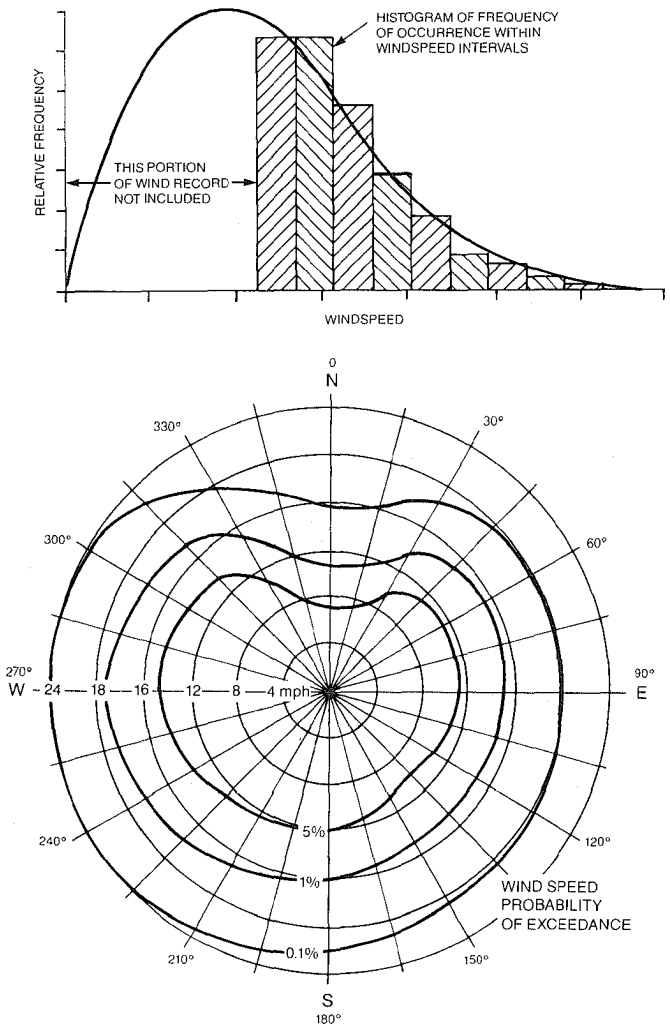

Fig. 11 Probability Distributions of Wind Speed and Direction

Accurate extrapolation of frequency distributions to rarely occurring high wind speeds requires special statistical techniques. Building codes for wind loading on structures contain information on estimating extreme wind conditions. For ventilation applications, extreme winds are usually not required, and the 99 percentile limit can be accurately estimated from airport data averaged over less than 10 years.

Estimating Wind at Sites Remote from Recording Stations

Many building sites are located far from the nearest long-term wind recording site, usually an airport. To estimate wind conditions at such sites, the terrain surrounding both the anemometer site and the building site should be checked. In the simplest case of flat or slightly undulating terrain with few obstructions extending for large distances around and between the anemometer site and building site, recorded wind data can be assumed to be representative of that at the building site.

In cases where the only significant difference between the airport recording site terrain and the terrain at the building site is surface roughness, the mean wind speed profile can be adjusted to yield approximate wind velocities at the building site (Figure 12). The constant A_o in Equation (9) corrects for the changes in a fully developed wind profile from an airport site in open terrain to the roughness of the building site. Swami and Chandra (1987) give a general procedure that can be applied to other values of the wind speed power law exponent a and boundary layer thickness δ.

If the building is near the upwind edge of the change in roughness, it may not be completely covered by the new boundary layer. The approximate height δ_2 of this internal boundary layer is given in Table 1 (Elliot 1958).

In the process of development, the mean hourly wind speed profile over the new terrain roughness Z_{o2} has approximately the same characteristics as the fully developed profile from Figure 4 below δ_2 and the same characteristics as the fully developed profile over Z_{o1} for heights above δ_2. The height δ_2 of the new internal boundary layer will become constant when it equals the fully developed heights shown in Figure 4.

In addition to changes in surface roughness, several other factors are important in causing the wind speed and direction at a building site to differ from values recorded at a nearby airport. Wind speeds can be 50% higher than airport data for buildings on hill crests or in valleys where the wind is channeled along a valley. Shelter in the lee of hills and escarpments can reduce speeds by a factor of 2 below values at nearby flat airport terrain.

Table 1 Depth of Internal Boundary Layer δ_2 at Transition in Roughness (see Figure 12)

	Z_{o1}, in.	Z_{o2}, in.	Travel Distance over Z_{o2} 160 ft	1600 ft	16000 ft
Open country to suburb	0.8	8	36	230	140
Suburb to open country	8	0.8	30	180	150
Suburb to city center	8	79	62	360	2300
City center to suburb	79	8	43	295	1640

Solar heating of valley slopes can cause light winds of 200 to 800 fpm to occur as warm air flows upslope. At night, cooling of the ground by heat radiation can produce these speeds as cold air drains downslope. In general, rolling terrain will experience a smaller fraction of low speeds than nearly flat terrain.

When the wind is calm or light in the rural area surrounding a city, urban air tends to rise in a buoyant plume over the city center. This rising air, heated by man-made sources and higher solar absorption in the city, is replaced by air sucked toward the city center from the edges. In this way, the urban heat island can produce light wind speeds and direction frequencies significantly different than measurements at an airport.

A rough guideline is that only wind speeds of 9 mph or greater at the building site can be transferred to a nearby airport using Equations (9), (10), and Figure 3 to determine their frequency of occurrence. Wind direction occurrence frequency at a building site should be inferred from airport data only if the two locations are on the same terrain, with no terrain features that could alter wind direction between them.

Where the only change in terrain between the building site and the airport anemometer is a topographic feature, such as a hill, ridge, or escarpment, adjustments can be made to the mean hourly wind speed profile using amplification factors from data collected by Simiu and Scanlan (1986) and Cook (1986). In more complex terrain with more than one hill, both wind speed and direction may be significantly different from those at the distant recording site. Here, building site wind conditions should not be estimated from airport data. Options in these cases are either to establish an on-site wind recording station or to commission a detailed wind tunnel correlation study between the building site and long-term airport wind observations.

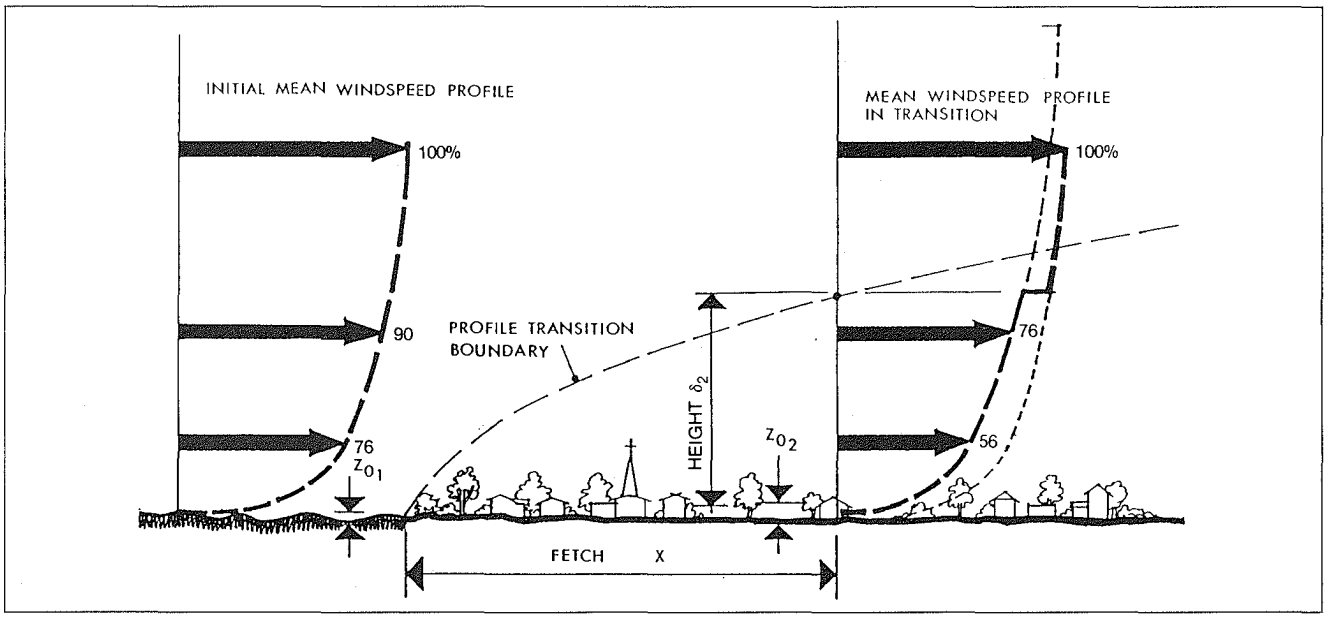

Fig. 12 Development of Internal Boundary Layer Following Change in Terrain Roughness

WIND EFFECTS ON SYSTEM OPERATION

With few exceptions, building intakes and exhausts cannot be located or oriented for a prevailing wind to assure ventilation and air-conditioning system operation. Wind can assist or hinder inlet and exhaust fans depending on their position on the building, but even in locations with a predominant wind direction, the ventilating system must perform adequately for all other directions. To avoid variability in system flow rates, use Figures 5, 6, 9, and 10 as a guide to placing inlets and exhausts in locations where the surface pressure coefficients do not vary greatly with the wind direction.

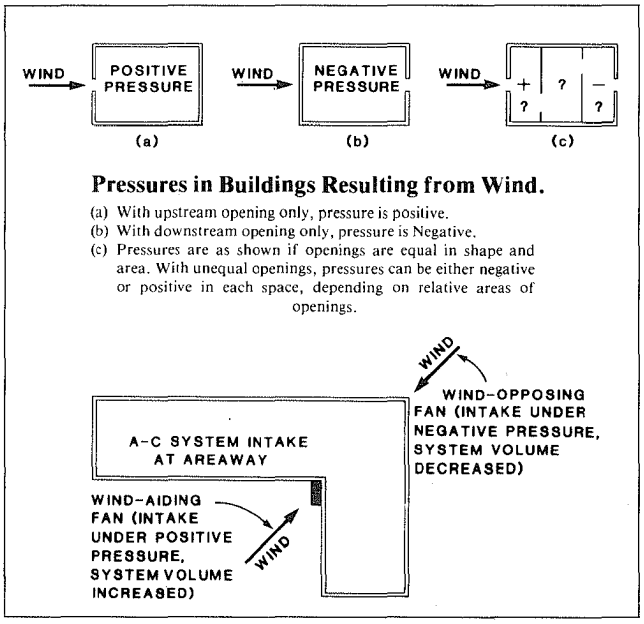
Cooling towers and similar equipment should be oriented to take advantage of prevailing wind directions, based on careful study of the meteorological data and flow patterns on the building for the area and time of year involved.

A building with only upwind openings is under a positive pressure (Figure 13). Building pressures are negative when there are only downwind openings. A building with internal partitions and openings is under various pressures depending on the relative sizes of the openings and the wind direction. With larger openings on the windward face, the building interior tends to remain under positive pressure; the reverse is also true (see Figures 5 through 8, and Chapter 23).

Airflow through a wall opening results from positive or negative external and internal pressures. Such differential pressures may exceed 0.5 in. of water during high winds. Supply and exhaust systems, and openings, dampers, louvers, doors, and windows make the building flow conditions too complex for most calculation. The opening and closing of doors and windows by building occupants add further complications. In determining $C_{p(in\text{-}out)}$ from Equation (11), the wind direction is more important than the position of an opening on a wall, as shown in Figures 5 and 6.

Natural and Mechanical Ventilation

With natural ventilation, wind may augment, impede, or sometimes reverse the airflow through a building. For large roof areas (Figure 2), the wind can reattach to the roof downstream from the cavity and thus reverse natural ventilation discharging out of monitor or similar windows. These reversals can be avoided by using stacks, continuous roof ventilators, or other exhaust devices in which the flow is augmented by the wind.



Pressures in Buildings Resulting from Wind.

(a) With upstream opening only, pressure is positive.
(b) With downstream opening only, pressure is Negative.
(c) Pressures are as shown if openings are equal in shape and area. With unequal openings, pressures can be either negative or positive in each space, depending on relative areas of openings.

Fig. 13 Sensitivity of System Volume to Locations of Building Openings, Intakes, and Exhausts

Mechanical ventilation is also affected by wind conditions. A low-pressure wall exhaust fan, 0.05 to 0.1 in. of water, can suffer drastic reduction in capacity. Flow can be reversed by wind pressures on windward walls, or its rate can be increased substantially when subjected to negative pressures on the lee and other sides. Clarke (1967), when measuring medium pressure air-conditioning systems, 1 to 1.5 in. of water, found flow rate changes of 25% for wind blowing into intakes on an L-shaped building compared to the reverse condition. Such changes in flow rate can cause noise at the supply outlets and drafts in the space served.

For mechanical systems, the wind can be thought of as producing a pressure in series with a system fan, either assisting or opposing it (Houlihan 1965). Where system stability is essential, the supply and exhaust systems must be designed for high pressures (about 3 to 4 in. of water) to minimize unacceptable variations in flow rate. To conserve energy, the system pressure selected should be consistent with system needs.

Building Pressure Balance

Proper building pressure balance avoids flow conditions that make doors hard to open, cause drafts, and prevent confining of contaminants to specific areas. Although the supply and exhaust systems in an area may be in nominal balance, wind can upset this balance, not only because of the changes in fan capacity but also by superimposing infiltrated or exfiltrated air or both on the area. The effects can make it impossible to control environmental conditions. Where building balance and minimum infiltration are important, consider the following:

- Fan system design with pressure adequate to minimize wind effects.
- Controls to regulate flow rate or pressure or both.
- Separate supply and exhaust systems to serve each building area requiring control or balance.
- Doors (possibly self-closing) or double-door air locks to noncontrolled adjacent areas, particularly outside doors.
- Sealing windows and other leakage sources and closing natural vent openings.

System volume and pressure control is described in Chapter 41 of the 1991 ASHRAE *Handbook—Applications*. Such control is not possible without adequate system pressure for both the supply and exhaust systems to overcome wind effects. Such a control system may require fan inlet or discharge dampers, fan speed or pitch control, or both.

Fume Hood Operation

Wind effects can interfere with safe hood operation. Supply (makeup) volume variations can cause disturbances at hood faces or a lack of adequate makeup air. Volume surges, caused by fluctuating wind pressures acting on the exhaust system, can cause momentary inadequate hood exhaust. If highly toxic contaminants are involved, such surging is unacceptable. The system should be designed to eliminate this condition. On low-pressure exhaust systems, it is impossible to test the hoods under wind-induced, surging conditions. These systems should be tested during calm conditions for safe flow into the hood faces; they should be rechecked by smoke tests during high wind conditions.

Minimizing Wind Effect on System Volume

Wind effect can be reduced by careful selection of inlet and outlet locations. Because wall surfaces are subject to a wide variety of positive and negative pressures, wall openings should be avoided when possible. When they are required, wall openings should be away from corners formed by building wings (Figure 13). Mechanical ventilation systems should operate at a pressure

high enough to minimize wind effect. Low-pressure systems and propeller exhaust fans should not be used with wall openings unless their ventilation rates are small or used in noncritical services such as storage areas.

Although roof air intakes within flow recirculation zones minimize wind effect on system flow rates best, current and future air quality in these zones must be considered. These locations should be avoided if a source of contamination exists or may appear in the future. The best area is near the middle of the roof because the negative pressure there is small and least affected by changes in wind direction (Figure 9). Avoid the edges of the roof and walls, where large pressure fluctuations occur. Either vertical or horizontal (mushroom) openings can be used. On large roof areas, where the intake may be outside the roof recirculation zone, mushroom or 180° gooseneck designs minimize impact pressure from wind flow. The frequently used 135° gooseneck or vertical louvered openings are undesirable for this purpose or for rain protection.

Exhausts discharging heated air or industrial contaminants should exhaust vertically through stacks, above the roof recirculation zone. Horizontal, louvered (45° down), and 135° gooseneck discharges are undesirable, even for heat removal systems because of their sensitivity to wind effect. A 180° gooseneck for systems handling hot air may be undesirable because of air impingement on tar and felt roofs. Vertically discharging stacks located in a recirculation region (except near a wall) have the advantage of being subjected only to negative pressure created by wind flow over the tip of the stack.

BUILDING INTERNAL PRESSURE AND FLOW CONTROL

In air-conditioning and ventilation systems for a building containing airborne contaminants, the correct airflow is toward the contaminated areas. Airflow direction is maintained by controlling pressure differentials between spaces. In a laboratory building, for example, peripheral rooms such as offices and conference rooms are maintained at a positive pressure, and laboratories at a negative pressure, both with reference to corridor pressure. Pressure differentials between spaces are normally obtained by balancing the air-conditioning and ventilation supply system airflows in the spaces in conjunction with the exhaust systems in the laboratories, with differential pressure instrumentation to control the airflow. Chapter 41 of the 1991 ASHRAE *Handbook—Applications* has further information on controls.

Airflow in corridors is sometimes controlled by an outdoor reference probe that senses static pressure at doorways and air intakes. The differential pressure measured between the corridor and the outside may then signal a controller to increase or decrease airflow to the corridor. Unfortunately, it is difficult to locate an external probe where it will sense the proper external static pressure. High wind velocity and resulting pressure changes around entrances can cause great variations in pressure. Care must be taken to ensure that the probe is unaffected by wind pressure.

The pressure differential for a room adjacent to a corridor can be controlled by using the corridor pressure as the reference. Outdoor pressure cannot control pressure differentials within rooms, even during periods of relatively constant wind velocity and pressure. A single pressure sensor can measure the outside pressure at one point only and may not be representative of pressures elsewhere.

ATMOSPHERIC DISPERSION OF BUILDING EXHAUST

A building exhaust system is frequently used to release a mixture of building air and pollutant gas at concentration C_e (mass of pollutant per volume of air) into the atmosphere through a stack or vent on the building. The exhaust mixes with atmospheric air to produce a pollutant concentration C, which may contaminate an air intake or receptor if the concentration is larger than some specified allowable value C_{allow} (Figure 1). The dilution D between source and receptor is defined as

$$D = C_e/C \tag{12}$$

The dilution increases with distance from the source, starting from its initial value of unity. If C is replaced by C_{allow} in Equation (12), the required atmospheric dilution D_{req} to meet the allowable concentration at the intake (receptor) is C_e/C_{allow}. The exhaust (source) concentration is given by

$$C_e = m/Q_e = m/(A_e V_e) \tag{13}$$

where

m = pollutant release rate, lb/s
$Q_e = A_e V_e$ = total exhaust volume flow rate, ft^3/s
A_e = exhaust face area, ft^2
V_e = exhaust face velocity, ft/s

The concentration units of mass/mixture volume are appropriate for gaseous pollutants, aerosols, dusts, and vapors. The concentration of gaseous pollutants is usually stated as a volume fraction f (contaminant volume/mixture volume), or ppm (parts per million) if the volume fraction is multiplied by 10^6. The pollutant volume fraction f_e in the exhaust is

$$f_e = Q/Q_e \tag{14}$$

where Q is the volume release rate of the contaminant gas, and Q_e is the total exhaust mixture volume flow rate, both calculated at the exhaust temperature T_e.

If the exhaust gas mixture has a relative molecular mass close to that of air, the volume concentration dilution factor $D_v = f_e/f$ may be calculated from the mass concentration dilution by

$$D_v = (T_e/T_a)D \tag{15}$$

where T_e is the exhaust air absolute temperature, T_a is the outdoor ambient air absolute temperature, and f_e is the pollutant volume fraction in the exhaust air. Many building exhausts are close enough to ambient temperature to assume volume fraction and mass concentration dilutions D_v and D are equal.

Exhaust Gas Concentrations at Air Intakes

The dispersion of pollutants from a building exhaust depends on the combined effect of atmospheric turbulence in the wind approaching the building and turbulence generated by the building itself. This building-generated turbulence is most intense in and near the flow recirculation zones that occur on the upwind edges of the building (Figures 2 and 3). Because of turbulence and distortion of the wind streamlines by the building, the concentration caused by a source near a building cannot be estimated accurately by the design procedures developed for tall isolated stacks. Meroney (1982), Wilson and Britter (1982), Hosker (1984), and Halitsky (1982) review gas diffusion near buildings.

When the exhaust source is in or near a flow recirculation zone, contours of the normalized concentration coefficient $K_c = CU_H HW/Q$, developed from wind tunnel model studies on buildings of similar shape, as shown in Figure 14, may be used. Halitsky (1985) gives details of this technique. Surface concentrations for block buildings with uncapped exhaust vents and short stacks in a uniform nonturbulent airstream are reported by Halitsky (1963).

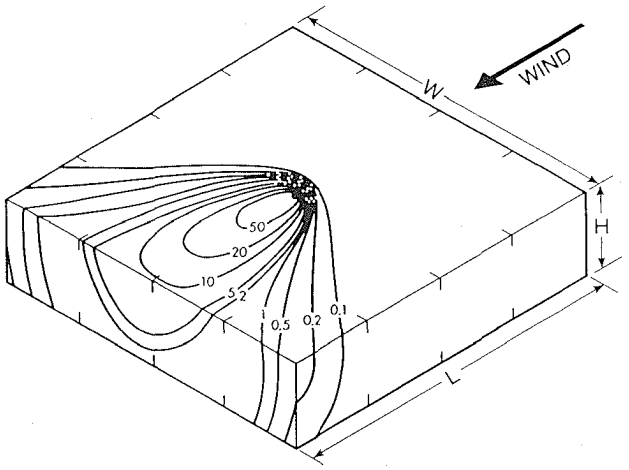


Fig. 14 Normalized Concentration Contour for Central Vent on Roof of Low-Rise Building
(Wilson 1976)

Jet diameters and emission velocities were large enough to project the exhaust plume above the roof and sometimes through the recirculation cavity.

ESTIMATING INTAKE CONTAMINATION

If a representative configuration with published surface concentration coefficients K_c cannot be found to match the existing building, available data may be used to estimate the minimum dilution observed at the same receptor distance from the source.

The most important variables determining minimum dilution are the exhaust to intake stretched-string distance S and the effective stack height h_s, both of which are defined in Figure 3. Only the stack height extending above large rooftop obstacles such as penthouses and architectural barriers should be used to define the effective stack height.

The stretched-string distance S is defined as the shortest length of string connecting the point on a stack where $h_s = 0$ to the nearest point on an air intake. The point where $h_s = 0$ is defined as the height of obstacles close to the stack, as shown in Figure 3, or the boundary of any roof recirculation region through which the stack passes.

All the following equations for D_{min} were developed from wind tunnel simulations on low-rise buildings for exposures equivalent to 10-min averaging times in the atmosphere, and with nonbuoyant exhaust jets from roof vents. If the exhaust gases are hot, buoyancy increases the rise of the exhaust gas mixture and produces lower concentrations at roof level. By neglecting buoyant plume rise, the D_{min} equations have an inherent factor of safety, particularly at low wind speed where buoyancy is most important.

The averaging time t_a over which exhaust gas concentration exposures are measured is also important in determining minimum dilution. As the averaging time increases, the exhaust gas plume meanders more from side to side, thus reducing the time-averaged concentration at an intake location. Wilson (1985) describes the effect of changing the averaging time over a range of about 3 min to 3 h, estimated by adjusting the 10-min values given in Equations (17) to (25) using

$$D_{min,1}/D_{min,2} = (t_{a1}/t_{a2})^{0.33} \tag{16}$$

The ratio of minimum dilution at any two averaging times t_{a1} and t_{a2} applies for $S/A^{0.5} > 10$ to allow the exhaust jet to begin meandering. Where the exhaust and intake are both located in the same flow recirculation region, dilution will be less sensitive to averaging time than predicted by Equation (16). In this case, assume the D_{min} values for 3-min averages also apply for averaging times from 3 to 60 min. Use Equation (16) to adjust the 10-min values in Equations (17) to (25) to 3-min values for this flow recirculation situation.

Strong Jets in Flow Recirculation Cavity

For block buildings with surface vents or short stacks that produce significant jet rise because of their large diameter, high emission velocity, and free discharge, the equation for minimum dilution at a surface intake on the same building or on the jet centerline above the building roof is given by Halitsky (1963)

$$D_{min} = [\alpha + 0.11(1 + 0.2\alpha)S/A_e^{0.5}]^2 \tag{17}$$

where α is a numerical constant related to building shape, emission velocity ratio V_e/U_H, building orientation to the wind, and stack height. Values of α can be found in Halitsky (1963). The smallest D_{min} occurs along the elevated centerline of the jet plume, where $\alpha = 1.0$ is the appropriate value. Larger values of D_{min} occur on the building surfaces, where the range of α is 2.0 to 20. The larger values are associated with greater stack height and buoyant exhaust. Halitsky (1963) gives the tested configuration that most closely resembles the one under consideration.

Strong Jets on Multiwinged Buildings

For a strong vertical exhaust with $V_e/U_H \cong 2$ from surface vents or short stacks on the roof of a multiwinged building with different wing roof heights, Halitsky (1962, 1982) recommends

$$D_{min} = M(3.16 + 0.1S/A_e^{0.5})^2 \tag{18}$$

where M is an intake location factor with values of $M = 1.5$ when the intake is on the same roof as the source, $M = 2.0$ when the source and intake are on different wings separated by an air space, and $M = 4.0$ when the intake is substantially lower than the source.

Surface Vents on Flat-Roofed Buildings

For buildings with exhausts of zero stack height on a flat roof, the minimum dilution at a roof or wall intake is given by Wilson and Chui (1985, 1987) and Chui and Wilson (1988) as

$$D_{min,o} = [D_o^{0.5} + D_s^{0.5}]^2 \tag{19}$$

where

$$D_o = 1 + 7.0\beta(V_e/U_H)^2 \tag{20}$$

and

$$D_s = B_1(U_H/V_e)(S^2/A_e) \tag{21}$$

$D_{min,o}$ is the minimum dilution for a roof level exhaust, D_o is the apparent initial dilution at roof level, and D_s is the distance dilution caused by the combined action of building and atmospheric turbulence. The initial dilution D_o is caused by internal turbulence in the exhaust jet (Halitsky 1962, 1966). The wind speed U_H at wall height is calculated from local airport weather data using Equations (9) and (10).

Equation (20) was developed for exhaust velocity to wind speed ratios from $V_e/U_H = 0$ to 2, and should be used cautiously above this value. For vertically directed uncapped exhausts, the capping factor $\beta = 1.0$; for capped, louvered, or downward-facing exhausts, it is $\beta = 0$. The distance dilution parameter B_1 depends on the exhaust jet trajectory, and the intensity of turbulence in the approach wind and generated by the building. For flat-roofed buildings in low-rise urban surroundings, $B_1 = 0.0625$ for all

wind directions, when the exhaust is uncapped ($\beta = 1$) and $V_e/U_H > 0.5$. A value of $B_1 = 0.0204$ should be used if $V_e/U_H < 0.5$ or the stack is capped ($\beta = 1$) and the wind is at 45° to the upwind wall, or if there is no significant atmospheric turbulence, for example, at roof level of high-rise buildings, or in flat rural surroundings [Wilson and Chui (1987), Chui and Wilson (1988)].

Equations (19), (20), and (21) imply that minimum dilution does not depend on the location of either the exhaust or intake, only on the distance S between them. This is true when exhaust and intake locations are on the same building wall or on the roof. The dilution may increase if the intake and exhaust are located on different faces, as indicated by the M factor in Equation (18). For roof exhausts with wall intakes, the results of Li and Meroney (1983) suggest that $B_1 \cong 0.20$ in Equation (21).

For buildings less than about 330 ft high and also less than twice as high as the surrounding buildings, atmospheric turbulence makes a significant contribution to exhaust gas dilution. Wilson (1976, 1977) gives surface concentration contours for flat-roofed buildings in a simulated approach wind typical of an urban area. Flush vents with small exhaust velocity make these results suitable for estimates for capped exhaust stacks or louvered exhaust vents.

The effect of atmospheric turbulence is relatively insignificant for high-rise buildings taller than 330 ft and also twice the average building height for 3000 ft upwind. On these high-rise buildings, where the effects of atmospheric turbulence are small, Wilson and Chui (1987) found that maximum surface concentrations for 10-min exposures were two to ten times higher than on an equivalent low-rise building. A dilution coefficient of $B_1 = 0.02$ should be used for high-rise buildings.

When exhaust from several collecting stations is combined in a single vent or in a tight cluster of stacks, the effective exhaust flow area A_e will increase, causing the minimum dilution in Equation (19) to decrease. To qualify as a cluster, the stacks must all lie within a two-stack diameter radius of the middle of the group. Stacks lined up in a row do not act as a single stack, as shown by Gregoric *et al.* (1982). However, the exhaust concentration C_e of each contaminant will decrease by mixing with other exhaust streams, and the plume rise will increase due to the higher momentum in the combined jets. For combined vertical exhaust jets, the roof level intake concentration C in Equation (12) will almost always be lower than the intake concentration caused by separate exhausts. Where possible, exhausts should be combined before release to take advantage of this increase in overall dilution.

Critical Wind Speed and Dilution

At very low wind speed, the exhaust jet from an uncapped stack will rise high above roof level, producing a large exhaust dilution D_{min} at a given intake location. Likewise, at high wind speed, the dilution will also be large because of the longitudinal stretching of the plume by the wind. Between these extremes, a critical wind speed exists at which the least dilution will occur for a given exhaust and intake location. This critical, absolute minimum dilution D_{crit} may be used to determine if an exhaust vent will be safe under all wind conditions. The critical wind speed for an uncapped vertical exhaust ($\beta = 1.0$) can be evaluated by finding the absolute minimum in Equations (19), (20), and (21). It is closely approximated by

$$U_{crit,o}/V_e = 2.9B_1^{-0.33}(S/A_e^{0.5})^{-0.67} \qquad (22)$$

where $U_{crit,o}$ is the critical wind speed producing the smallest minimum dilution for an uncapped vertical exhaust with negligible stack height. This critical dilution $D_{crit,o}$ may be found by using Equation (22) in Equation (19). For $S/A_e^{0.5} > 5$, this minimum is closely approximated by

$$D_{crit,o} = 1 + 7.0B_1^{0.67}(S/A_e^{0.5})^{1.33} \qquad (23)$$

The critical dilution in Equation (23) depends only on distance from the exhaust and not on the exhaust velocity V_e. However, increasing the exhaust velocity increases the critical wind speed in Equation (22), usually causing this worst-case critical dilution to occur less frequently.

To assess the severity of the hazard caused by intake contamination, it is useful to know how often the worst case D_{crit} is likely to occur. The number of hours per year during which the dilution is no more than a factor of 2 higher than the critical minimum value may be estimated from weather records by finding the fraction of time that the wind speed lies in the range from 0.5 $U_{crit,o}$ to 3.0 $U_{crit,o}$ (Wilson 1982, 1983). This fraction is then multiplied by the fraction of time the local wind direction lies in a sector ± 22.5° on each side of the line joining the exhaust and intake location.

EXHAUST STACK DESIGN

Before discharge, exhaust contamination should be reduced by filters, collectors, and scrubbers. Central exhaust systems that combine flows from many collecting stations should always be used where safe and practical. By combining several exhaust streams, central systems dilute intermittent bursts of contamination from a single station. However, in some cases, separate exhaust systems are mandatory. The nature of the contaminants to be combined, the recommended industrial hygiene practice, and the applicable safety codes need to be considered. Halitsky (1966) and Briggs (1984) present methods for estimating the trajectory of jets and the subsequent dispersion of jet plumes.

Separate exhaust stacks should be grouped in a tight cluster to take advantage of the larger plume rise of the resulting combined jet. In addition, a single stack from a central exhaust system or a tight cluster of stacks allows building air intakes to be placed as far as possible from the exhaust location. As shown in Figure 3, the effective stack height h_s is the portion of the exhaust stack that extends above local recirculation zones and upwind and downwind obstacles. Wilson and Winkel (1982) demonstrated that stacks terminating below the level of adjacent walls and architectural enclosures do not effectively reduce roof-level exhaust contamination. To take full advantage of their height, stacks should be located on the highest roof of a building. Where architectural enclosures are used to mask rooftop equipment, stacks must extend above the height H_c of the flow recirculation zone over the enclosure to prevent exhaust contamination of equipment within the enclosure.

Required Stack Exhaust Velocity

High stack discharge velocity and temperature increase plume rise and reduce intake contamination by increased jet dilution and by the elevated plume trajectory. However, high discharge velocity is a poor substitute for increased stack height.

As shown in Figure 15, stacks should have vertically directed uncapped exhaust jets. Stack caps which deflect the exhaust jet have a detrimental effect on both minimum dilution and critical wind speed. In any case, conical stack caps often do not eliminate rain, because rain does not usually fall straight down. Changnon (1966) shows that periods of heavy rainfall are often accompanied by high winds that deflect the raindrops under the cap and into the stack. A stack velocity of about 2500 fpm prevents condensed moisture from draining down the stack and keeps rain from entering the stack. Even when there are drains in the stack, the exhaust velocity should be maintained above 2000 fpm to provide adequate plume rise and jet dilution. Where stack condensate is corrosive, the body of the stack should be sized for a velocity of 1000 fpm

or less, and a drain provided for the condensate (Anonymous 1964). The stack tip should have a converging cone (Figure 15B) to provide the required high-velocity discharge of 2000 to 3000 fpm. For intermittently operated systems, protection from rain and snow should be provided by stack drains as shown in Figures 15F through 15J.

Stack Height to Avoid Exhaust Entrainment

To avoid entrainment of exhaust gases into the wake, stacks must terminate above the flow recirculation height H_c. Where stacks or exhaust vents discharge within this recirculation region, gases rapidly diffuse to the roof and may enter ventilation intakes or other openings. Figure 1 shows that this effluent will flow into the zone of recirculating flow behind the downwind face and will, in some cases, be brought back up onto the roof.

A high velocity exhaust with V_e at least 1.5 times as large as the wind speed U_H at roof height is essential not only to provide good initial dilution near the stack, but also to avoid stack wake downwash, which can reduce or eliminate plume rise. Downwash of the exhaust into the stack wake, shown in Figure 16, is caused by the low-pressure region which develops in the wake on the lee side of the stack. In situations where exhaust velocity cannot be maintained at a value larger than 1.5 times the wind speed, an additional downwash height h_d (see Figure 16) should be added to the stack height h_s. For a vertically directed jet from an uncapped stack ($\beta = 1.0$), Briggs (1973) recommends

$$h_d = 2.0d(1.5\beta V_e / U_H) \qquad (24)$$

for $V_e/U < 1.5$, where $d = (4A_e/\pi)^{0.5}$ is the effective stack diameter. Rain caps are frequently used on stacks of gas-and oil-fired furnaces and package ventilation units. These units will have $\beta = 0$, so $h_d = 3.0d$, and this should be added to the nominal height h_s to avoid flue gas contamination of roof-mounted equipment and air intakes.

The design procedure for selecting an appropriate stack height starts by calculating the height h_{sc} of a stack with a rain cap and, therefore, no plume rise. For an uncapped vertical exhaust, the minimum rise h_r of the bent-over exhaust jet is estimated, and the

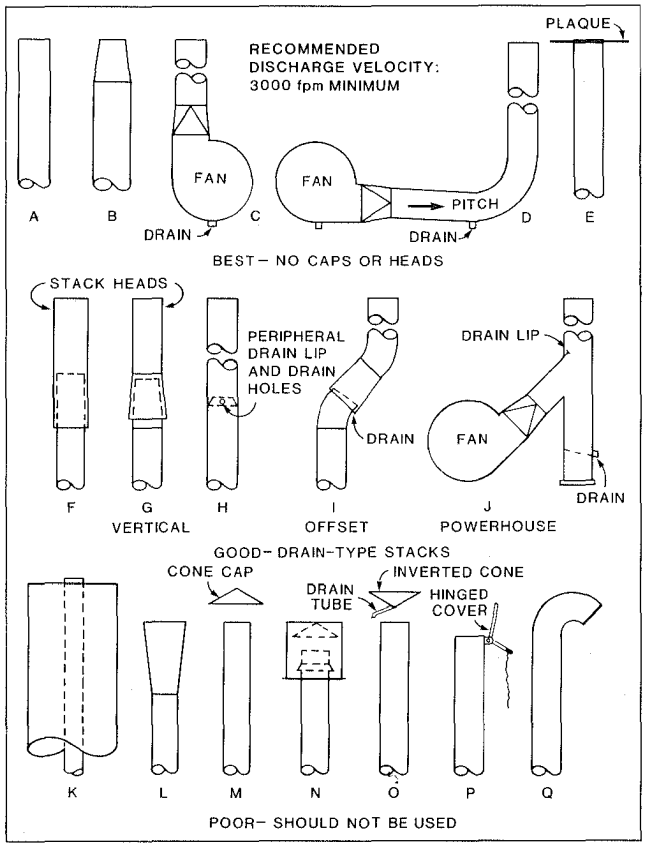

Fig. 15 Stack Designs Providing Vertical Discharge and Rain Protection

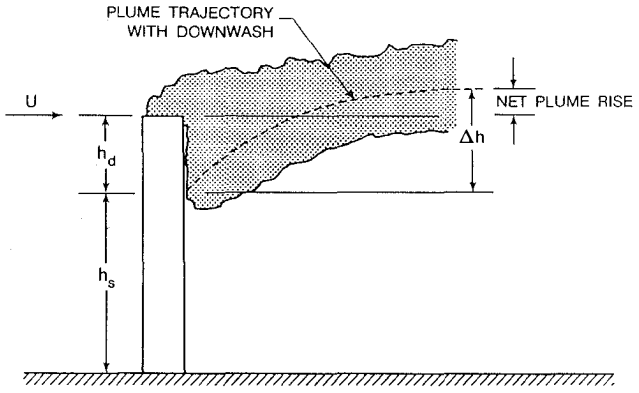

Fig. 16 Reduction of Effective Stack Height by Stack Wake Downwash

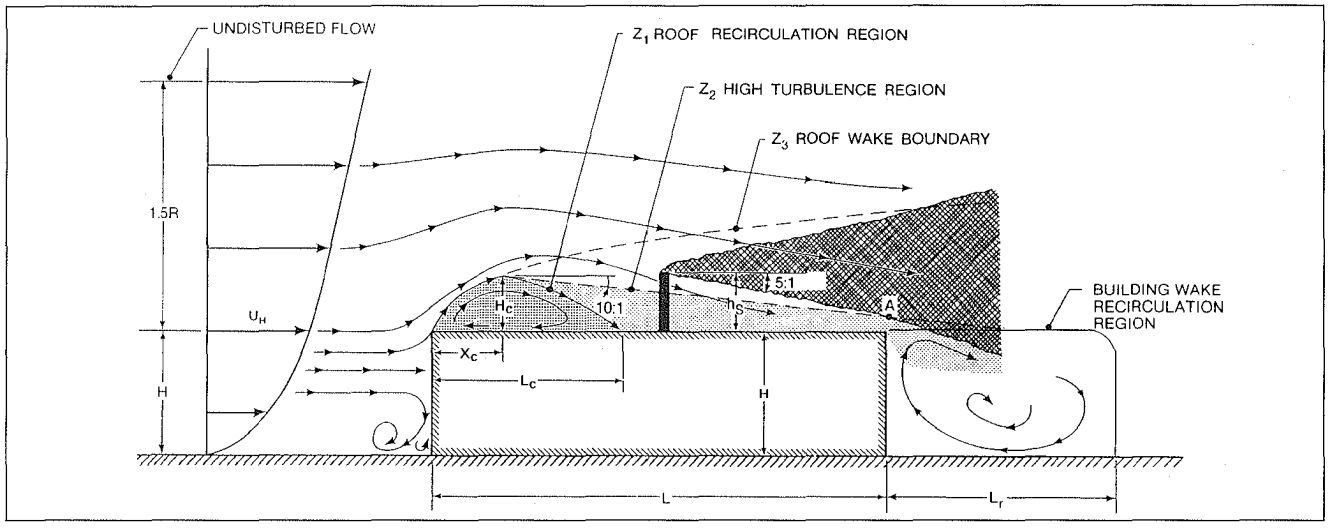

Fig. 17 Design Procedure for Required Stack Height to Avoid Contamination
(Wilson 1979)

capped height h_{sc} is lowered by an amount h_r to give credit for plume rise (see Figure 16).

The capped stack height h_{sc} required to avoid excessive exhaust gas reentry is estimated by assuming that the plume spreads upward and downward from h_{sc} with a 1:5 slope (11.3°), as shown in Figure 17. The first step is to raise the capped height h_{sc} until the lower edge of the 1:5 sloping plume avoids contact with all recirculation (zone 1) boundaries on rooftop obstacles such as air intake housings, architectural screens, or penthouses. The size of these recirculation zones, shown in Figures 3 and 17, are calculated using Equations (2), (3), and (4).

If air intakes are located on the downwind wall, the lower edge of the plume, sloping down at 1:5, must lie above the downwind edge of the roof when a nontoxic exhaust contaminant, such as an odor or water vapor, is being dealt with. For a toxic contaminant that requires a large dilution factor at the wall intake, the lower edge of the plume should lie above the flow recirculation zone in the wake downwind of the building. The boundary of the building wake recirculation, shown in Figures 1, 3, and 17, is defined by a horizontal line extending a distance L_r from the downwind edge of the roof. The recirculation length L_r is calculated from Equation (5).

For an uncapped stack, the plume rise h_r due to the vertical momentum of the exhaust is estimated from Briggs (1984) as

$$h_r = 3.0(V_e/U_H)d \tag{25}$$

where the wind speed U_H is the maximum design wind speed for which air intake contamination must be avoided. The required height h_s of the uncapped stack extending above local recirculation zones and obstacles is

$$H_S = h_{SC} - h_r + h_d \tag{26}$$

If the minimum recommended exhaust velocity of $V_e = 1.5\,U_H$ is maintained, plume downwash $h_d = 0$, and $h_r = 4.5d$; thus, an uncapped stack can be made $4.5d$ shorter than a capped one.

The largest flow recirculation, high turbulence, and wake regions occur when wind is normal to the upwind wall of the building. Required stack heights should be the largest of the heights determined for all four directions for which the wind is normal to a building wall.

Estimating Critical Dilution for Exhaust Stacks

The geometric design for avoiding excessive contamination does not give any estimate of the worst case critical dilution factor D_{crit} between the stack and an air intake. In this section, D_{crit} will be estimated for a predetermined stack height.

An increase in stack height or in exhaust velocity ratio V_e/U_H reduces roof-level contamination by keeping the high concentrations on the plume centerline far enough above the roof so that the intakes see only intermittent concentrations in the fringes of the plume. In addition, stack height or high exhaust velocity increases the critical wind speed at which the absolute minimum dilution occurs. This higher critical wind speed often reduces significantly the number of hours per year that high intake contamination (*i.e.*, low dilution) will be observed.

Using a Gaussian plume dispersion equation, with a plume spread standard deviation of $0.14S$, and an uncapped vertical exhaust jet with no buoyancy and with plume rise inversely proportional to wind speed, the critical wind speed U_{crit} at which the smallest minimum dilution D_{crit} observed is

$$\frac{U_{crit,o}}{U_{crit}} = (Y + 1)^{0.5} - Y^{0.5} \tag{27}$$

where $U_{crit,o}$ is the critical wind speed for a flush (zero stack height) vertical exhaust, computed from Equation (22). The influence of stack height on the worst case critical dilution for the standard 10-min exposure time may be calculated from

$$\frac{D_{crit}}{D_{crit,o}} = \frac{U_{crit}}{U_{crit,o}} \exp[Y + Y^{0.5}(Y+1)^{0.5}] \tag{28}$$

where $Y = 12.6(h_s/S)^2$, and $D_{crit,o}$ is the dilution at critical wind speed for a flush vertical roof exhaust with no stack height, from Equation (23). Equations (27) and (28) are reliable only for $Y < 2.0$. Close to the stack, where $Y > 2.0$, use $Y = 2.0$ in Equations (27) and (28). Because both wind speed and turbulence intensity vary strongly with height above the building roof, the plume rise of the exhaust jet may not be inversely proportional to wind speed; normally its behavior is between $\Delta h \propto U^{-0.4}$ and $U^{-1.0}$. Thus, Equations (27) and (28) are only approximations. Because buoyancy is not included, the added rise due to buoyancy provides a factor of safety, particularly at low wind speed.

Because Equations (27) and (28) give the effect of a stack relative to a flush exhaust with $h_s = 0$, they are useful for assessing the advantages of increasing stack height as a remedial measure. By comparing two different heights, this calculation allows the relative benefits of a stack to be estimated without knowing any details of the contaminant concentrations or exhaust velocity in the existing stack. For example, the stack height required using the simple geometrical design procedure in the following section will have h_s/S of at least 0.2. Equations (27) and (28) show that the critical wind speed U_{crit} for this stack height will be about a factor of 2 larger, and the critical dilution D_{crit}, about eight times more than for the vertical jet from an uncapped exhaust with zero effective stack height.

Example 1. The stack height h_s of the uncapped vertical exhaust on the building shown in Figure 3 must be specified to avoid excessive contamination of air intakes A and B by stack gases. The stack has a diameter d of 1.64 ft and an exhaust velocity V_e of 1770 fpm. It is located 52.5 ft from the upwind edge of the roof. The penthouse has its upwind wall (with intake A) located 98.4 ft from the upwind edge of the roof, a height of 13.1 ft, and a length of 23.0 ft in the wind direction. The top of intake A is 6.56 ft below the penthouse roof. The building has a height H of 49.2 ft and a length of 203 ft. The top of intake B is 19.7 ft below roof level. The width (measured into the page) of the building is 164 ft, and the penthouse is 29.5 ft wide. What are the required stack heights h_s for both nontoxic and highly toxic exhaust contaminants for a design wind speed specified at a factor of 2 higher than the annual average hourly wind speed of 9.32 mph at a nearby airport with anemometer height H_{ref} of 32.8 ft? The building is located in unshielded suburban terrain.

Solution: The first step is to set the height h_{sc} of a capped stack by projecting lines with 5:1 slopes upwind from points of potential plume impact. For intake A, the highest point of impact is the top of the recirculation zone on the roof of the penthouse. To find the height of this recirculation zone, start with Equation (1).

$$R = (13.1)^{0.67}(29.5)^{0.33} = 17.2 \text{ ft}$$

Then use Equations (2) and (3):

$$H_c = 0.22(17.2) = 3.77 \text{ ft}$$
$$X_c = 0.5(17.2) = 8.60 \text{ ft}$$

With the 5:1 slope of the lower plume boundary shown in Figure 17, the capped stack in Figure 3 must be

$$h_{sc} = 0.2(98.4 - 52.5 + 8.60) + 3.77 = 14.7 \text{ ft}$$

above the penthouse roof to avoid intake A. For intake B on the downwind wall, the plume boundary from the stack in Figure 3 must lie above the end of the roof for nontoxic exhaust gas or the end of the building flow recirculation zone for highly toxic exhaust gas. For this recirculation zone, from Equation (1):

$$R = (49.2)^{0.67}(164)^{0.33} = 73.2 \text{ ft}$$

Then, from Equation (5)

$$L_r = 1.0(73.2) = 73.2 \text{ ft}$$

Thus, for a highly toxic exhaust, the capped stack height to avoid contamination at intake B is

$$h_{sc} = 0.2(203 - 52.5 + 73.2) - 13.1 = 31.7 \text{ ft}$$

above the penthouse roof. For a nontoxic exhaust

$$h_{sc} = 0.2(203 - 52.5) - 13.1 = 17.1 \text{ ft}$$

The required stack height is set by the condition of avoiding contamination of intake B, because intake A requires only a 14.7 ft capped stack. Credit for plume rise h_r from the uncapped stack requires the building wind speed U_H at $H = 49.2$ ft to be calculated. The design airport wind speed $U_{met} = 18.6$ mph $= 1640$ fpm at $H_{ref} = 33$ ft has been specified. From Figure 4, $A_o = 0.60$ and $a = 0.28$ at the suburban building site, so from Equations (9) and (10)

$$U_{ref} = 0.60(1640) = 984 \text{ fpm}$$

and

$$U_H = 984(49.2/32.8)^{0.28} = 1102 \text{ fpm}$$

Because $V_e/U_H = 1770/1102 = 1.61$ is greater than 1.5, there is no plume downwash, and $h_d = 0$ from Equation (24). Using Equation (25), the plume rise at the design wind speed is

$$h_r = 3.0(1.61)(1.64) = 7.92 \text{ ft}$$

Deducting this rise from the uncapped height h_{sc} using Equation (25) for intake B

$$h_s = 17.1 - 7.92 = 9.18 \text{ ft}$$

for nontoxic exhaust gas, and

$$h_s = 31.7 - 7.92 = 23.8 \text{ ft}$$

for highly toxic exhaust gas. As shown in Figure 3, both these stack heights are measured above the roof of the nearby penthouse. Adding the 13.1 ft penthouse height sets the required stack heights at 22.2 ft and 37.1 ft above roof level.

Example 2. The uncapped stack from Example 1, with $h_s = 9.18$ ft above the penthouse roof is used to exhaust a toxic contaminant, the stack gas concentration of which must be diluted by 1000:1 to be considered safe for 60-min exposures. Calculate the critical minimum dilution factor D_{crit} and the critical wind speed U_{crit} for contamination for intakes A and B. Is the stack height of 9.18 ft sized in Example 1 for nontoxic exhaust sufficient to handle this toxic substance?

Solution: At intake A, the stretched-string distance is:

$$S_A = [(98.4 - 52.5)^2 + (6.56)^2]^{0.5} = 46.3 \text{ ft}$$

and the exhaust area of the 1.64 ft diameter stack is $A_e = 2.11$ ft^2. The first step is to determine the critical wind speed and dilution for an uncapped stack with $h_s = 0$. Assuming that V_e/U_H will be greater than 0.5, a dilution constant $B_1 = 0.0625$ is chosen from the recommended values in the text following Equation (21). The normalized exhaust to intake distance is

$$S_A/A_e^{0.5} = 46.3/(2.11)^{0.5} = 31.8$$

and $V_e = 1770$ fpm is specified, so Equation (22) yields

$$U_{crit,o} = 1770(2.9)(0.0625)^{-0.33}(31.8)^{-0.67} = 1263 \text{ fpm}$$

so that the ratio $V_e/U_H = 1770/1263 = 1.40$ meets the requirement of being greater than 0.5, used to set $B_1 = 0.0625$. From Equation (23), the critical dilution for zero stack height is

$$D_{crit,o} = 1 + 7.0(0.0625)^{0.67}(31.8)^{1.33} = 110$$

at intake A. The effect of stack height is calculated from Equations (27) and (28) for the 9.18 ft height, at intake A

$$Y = 12.6(9.18/46.3)^2 = 0.49$$

$$U_{crit} = 1260/[(0.49 + 1)^{0.5} - (0.49)^{0.5}] = 2420 \text{ fpm}$$

$$D_{crit} = 110(2420/1260) \exp[0.49 + (0.49)^{0.5}(0.49 + 1)^{0.5}] = 808$$

The stack has increased the critical wind speed to a very high, infrequently occurring value of 12.3 m/s or 44.3 km/h, and increased the critical worst case dilution by more than a factor of 7. To convert the dilution from a 10-min exposure time (which applies to all the equations in this chapter), to a 60-min exposure, use Equation (16)

$$D_{crit} = 808(60/10)^{0.33} = 1460$$

showing that the stack produces adequate dilution at intake A.

Repeating the calculations for intake B, the stretched-string distance S_B in Figure 3 is

$$S_B = 45.9 + 23.0 + [(82.0)^2 + (13.1)^2]^{0.5} + 19.7 = 172 \text{ ft}$$

and the normalized distance is

$$S_B/A_e^{0.5} = 172/(2.11)^{0.5} = 118$$

Using Equations (22) and (23) for intake B

$$U_{crit,o} = 1770(2.9)(0.0625)^{-0.33}(118)^{-0.67} = 525 \text{ fpm}$$

$$D_{crit,o} = 1 + 7.0(0.0625)^{0.67}(118)^{1.33} = 623$$

For the stack with $h_s = 9.18$ ft, at intake B,

$$Y = 12.6(9.18/172)^2 = 0.0356$$

and Equations (27) and (28) yield

$$U_{crit} = 525/[(0.0356 + 1)^{0.5} - (0.0356)^{0.5}] = 633 \text{ fpm}$$

$$D_{crit} = 808(633/525) \exp[0.0356 + (0.0356)^{0.5}(0.0356 + 1)^{0.5}] = 1220$$

Intake B, further from the stack than intake A, has its critical wind speed increased by a factor of 1.2 and its critical dilution increased by a factor of 1.5 due to stack height. For a 60-min exposure, Equation (16) predicts that for the 9.1 ft stack height

$$D_{crit} = 1220(60/10)^{0.33} = 2200$$

which also meets the required 1000:1 dilution for the exhaust contaminant. This example shows that detailed dilution calculations may allow shorter stacks than the simpler but more conservative estimates using the 5:1 slope method of Example 1.

Intake and Exhaust Locations to Minimize Contamination

Inlets should be located to minimize reentry from contaminated sources, including heat, humidity, and dust that may affect system performance. In warm weather, the entry of water vapor from a cooling tower can significantly increase air-conditioning load and reduce the effectiveness of heat relief ventilation systems. In cold weather, freezing water vapor can damage equipment, and ice can block intake grilles and filters, substantially reducing performance. Inlets should be located away from hot exhausts that discharge horizontally or are deflected downward. Do not locate inlets near plumbing vents. Clarke (1965) notes that adequate exhaust dilution often requires larger separation distances between intake and exhaust than are specified in local building codes.

Changes and additions are often made to industrial and laboratory buildings. Initially satisfactory inlet and exhaust conditions can be the source of future unacceptable contaminant reentry. Exhaust outlets should not be located within enclosures or architectural screens because they hold building exhaust in their recirculation zones, increasing reentry of contaminated air and causing plugging and corrosion of heat exchangers. Restaurant kitchen

hood exhausts are particularly destructive in this respect. Intakes and contaminated exhaust outlets should never be located in the same enclosure.

When the wind is normal to the upwind wall, the streamline patterns in Figures 1 and 2 show that air flows up and down the wall, dividing at about half the wall height. The downward flow creates turbulence that stirs up dust and debris. Changnon (1966), Clarke (1967), and Houlihan (1965) have shown that the upward flow on the top half of the wall can carry raindrops up the wall during high winds. To take advantage of the natural separation of wind flow on the upper and lower half of a building, toxic or nuisance exhaust should be located on the upper one-third, and intakes on the lower one-third of the building, high enough above ground to avoid wind-blown dust, vegetation, and vehicle exhaust. In particular, intakes near vehicle loading zones should be avoided. Overhanging canopies on vehicle docks do not effectively prevent hot vehicle exhaust from rising to intakes above the canopy.

To protect intakes from contamination by wind-blown dust and debris, they are best located on the roof. If contaminated exhaust is discharged from several locations on a roof, the intakes should be sited to minimize contamination by exhaust gases. In this case, intakes should be placed as far away from exhausts as possible, except when most of the exhaust is discharged from a single location. In this case, the most effective location for intakes on the roof is at the base of a single high exhaust stack that discharges the contaminated exhaust high above the intake location. If possible, air intakes and exhausts should not be located near the edges of a wall or roof because of the pressure fluctuations occurring there.

HEAT REJECTION EQUIPMENT

Cooling towers and similar heat rejection devices are very sensitive to airflow around buildings. This equipment is frequently roof-mounted, with intakes close to the roof where air is considerably hotter and at a higher wet-bulb temperature than air that is not influenced by the roof. This can reduce the capacity of cooling towers and air-cooled condensers.

Heat exchangers often take in air on one side and discharge heated, moist air horizontally from the other side. For these horizontal flow cooling towers, changes in wind direction and velocity caused by immediately adjacent obstructions can drastically reduce equipment performance by reducing the airflow rate. Recirculation is even more serious than reduction in airflow rate to such devices. Recirculation of warm moist exhaust raises the inlet wet-bulb temperature, which reduces performance. Recirculation can be caused by local disturbance of the airflow by upwind obstructions or by a close downwind obstruction. The vertical discharge ducts may need to be extended to improve the effectiveness of this equipment.

SCALE MODEL SIMULATION AND TESTING

For many routine design applications, flow patterns, wind pressures, and exhaust dilution can be estimated using the data and equations set out in the previous sections. However, in critical applications, such as when health and safety are of concern, physical modeling or full-scale field evaluations may be required to obtain more accurate estimates. Measurements on small-scale models in wind tunnels or water channels can provide information for design prior to construction and an economical method of performance evaluation for existing facilities. Full-scale testing is not generally useful in the initial design process because of the time and expense required to obtain meaningful information. On the other hand, full-scale testing is useful for verifying data derived from physical modeling and for planning remedial changes to improve existing facilities.

Detailed accounts of physical modeling, field measurements and applications, and engineering problems resulting from atmospheric flow around buildings are available in the proceedings of conferences on wind engineering (see Bibliography).

The wind tunnel is the main tool used to assess and understand the airflow around buildings. A water channel can also be used. Models of buildings, complexes, and the local surrounding topography are constructed and tested in a simulated turbulent atmospheric boundary layer. The airflow, wind pressures, snow loads, structural response, or pollutant concentrations can then be measured directly by properly scaling the wind and exhaust flow characteristics. Weil *et al.* (1981), Petersen (1987a), and Dagliesh (1975) found generally good agreement between the results of wind tunnel simulations and corresponding full-scale data.

Similarity Requirements

Physical modeling is most appropriate for applications involving small-scale atmospheric motions, such as recirculation of exhaust downwind of a laboratory, wind loads on structures, wind speeds around building clusters, snow loads on roofs, and airflow over hills. At present, winds associated with tornadoes, thunderstorms, and large-scale atmospheric motion cannot be simulated.

Snyder (1981) gives guidelines for fluid modeling of atmospheric diffusion. This report contains explicit directions and should be used whenever designing wind tunnel studies to assess concentration levels due to air pollutants. ANSI *Standard* A58.1 (1982) also provides guidance when wind tunnels are used for evaluating wind effects on structures.

A complete and exact simulation of the airflow over buildings and the resulting concentration or pressure distributions cannot be achieved in a physical model. This is not a serious limitation, however. Cermak (1971, 1976a,b), Snyder (1981), and Petersen (1987a,b) found that an accurate simulation of the transport and dispersion of laboratory exhaust can be achieved if the following criteria are used:

1. Match (equal in model and full scale) the exhaust velocity to wind speed ratio, V_e/U_H.
2. Match exhaust to ambient air density ratio, ρ_e/ρ_a.
3. Match exhaust Froude number, $\mathrm{Fr}^2 = \rho_r V_e^2/[(\rho_e - \rho_a)gd]$.
4. Ensure a fully turbulent stack gas flow; stack Reynolds number $Re_s = V_e d/\nu$ greater than 2000, or place an obstruction inside stack to enhance turbulence.
5. Ensure a fully turbulent wind flow with roughness Reynolds number $Re_z = U^* Z_o/\nu$ greater than 2.5.
6. Scale all dimensions and roughness by a common factor.
7. Match atmospheric stability by the bulk Richardson number (see Cermak 1975). For most applications related to airflow around buildings, neutral stratification is assumed, and no Richardson number matching is required.
8. Match mean velocity and turbulence distributions in the wind approaching the model.
9. Building wind Reynolds number $U_H R/\mu$ must be greater than 11,000 for sharp-edged structures, or greater than 90,000 for round-edged structures.

For wind speeds, flow patterns, or pressure distributions around buildings, only conditions 5 through 9 are necessary. Usually, each wind tunnel study requires a detailed assessment to determine which appropriate parameters to match in model and full scale.

In wind tunnel simulation of exhaust gas recirculation, the buoyancy of the exhaust gas (condition 3) is often not modeled. This allows using a high wind tunnel speed or a smaller model to achieve a high enough Reynolds number (conditions 4, 5, and 9). Neglecting buoyancy is justified if the density of building exhaust air is within 10% of the outdoor ambient air. Also, critical mini-

mum dilution D_{crit} occurs at wind speeds high enough to produce a well-mixed, neutrally stable atmosphere, allowing stability matching (condition 7) to be neglected. Omission of conditions 3 and 7 simplifies the test procedure considerably, reducing both testing time and cost.

Wind Simulation Facilities

Boundary layer wind tunnels are required for conducting most wind studies. The wind tunnel test section should be long enough so that a deep boundary layer that slowly changes with downwind distance can be established upwind of the model building. Boundary layer wind tunnels can be either open- or closed-circuit; an open-circuit tunnel is open to the ambient air at both ends, and a closed-circuit tunnel is attached at both ends so that the air continually circulates within the tunnel.

Other important wind tunnel characteristics include the width and height of the test section, range of wind speeds, roof adjustability, and temperature control. Larger models can be used in tunnels that are wider and taller which, in turn, gives better measurement resolution. Model blockage effects can be minimized by an adjustable roof height. Temperature control is required when atmospheric conditions other than neutral stability are to be simulated. Stable atmospheric conditions are simulated by heating the air and cooling the ground surface; unstable atmospheric conditions are simulated by heating the surface and cooling the air. Boundary layer characteristics appropriate for the site are established by using roughness elements on the tunnel floor that produce mean velocity and turbulence intensity profiles characteristic of the full scale.

Water as well as air can be used for the modeling fluid if an appropriate flow facility is available. Flow facilities may be in the form of a tunnel, tank, or open channel. Water tanks with a free surface ranging in size up to that of a wind tunnel test section have been used by towing a model (upside down) through the nonflowing fluid. Stable stratification can be obtained by adding a salt solution at the tank bottom. This technique does not permit development of a boundary layer and yields only approximate qualitative information on flow around buildings. Water channels can be designed to develop thick turbulent boundary layers similar to those developed in the wind tunnel. One advantage of such a flow system is ease of flow visualization, but this is offset by a greater difficulty in measurement of flow variables and concentrations.

Designing Model Test Programs

The first step in planning a test program is the selection of the model length scale. Choice of this scale depends on cross-sectional dimensions of the test section, dimensions of the building to be studied together with nearby neighboring buildings, and/or topographic features and thickness of the simulated atmospheric boundary layer. For tall buildings, the scale is often determined by the requirement that the ratio of boundary layer thickness to building height (δ/H) should be approximately equal for model and prototype. Strong wind boundary layers range in depth from 800 to 2000 ft for surroundings ranging from flat open terrain to suburbs of urban centers (see Figure 4). Boundary layer thicknesses in wind tunnel and water channel flow facilities have nominal depths ranging from 20 to 60 in; therefore, typical geometric scales range from about 150:1 to 1000:1.

For complexes of low to moderately tall buildings extending over a wide area, such as an industrial plant or an urban center, the scale is usually controlled by test section width. Most flow facilities available for testing purposes range in width from 40 to 160 in. If interest were focused on an area of 1600 ft radius, the scale could range from 1:1000 to 1:250 depending on the test section width. A large model size is desirable to meet minimum Reynolds and Froude number requirements; therefore, a wide test section provides advantages for testing purposes. In general, the model at any section should be small compared to the test section area so that blockage is less than 5%.

The test program must include specifications of the meteorological variables to be considered. These include wind direction, wind speed, and thermal stability. Data taken at the nearest meteorological station should be reviewed to obtain a realistic assessment of wind climate for a particular site. Ordinarily, local winds around a building, pressures, and/or concentrations are measured for 16 wind directions in 22.5° intervals. This is easily accomplished by mounting a building and its near surroundings on a turntable. If only local wind information and pressures are of interest, testing at one wind speed with neutral stability is sufficient.

In addition to source geometry, specifications of source characteristics must include the exhaust discharge face velocity V_e, the exhaust temperature, and the composition components of the effluent to determine exhaust density ρ_e. This information and meteorological data for the site determine a realistic range of values for the velocity ratio and the densimetric Froude number. Equality of model and prototype Froude numbers requires wind speeds of less than 100 fpm for testing. However, greater wind speeds may be needed to meet the minimum building Reynolds number requirement. Larger wind speeds are possible by using a density difference for the model effluent larger than the prototype difference. For effluent with positive buoyancy, it is convenient to use a mixture of air and helium plus a tracer. A mixture of air and carbon dioxide plus a tracer may be used to simulate a negatively buoyant effluent.

The following elements should be considered as part of a quality assurance plan for testing:

- Accuracy of scale models?
- Boundary layer similarity compared to full-scale wind and turbulence profiles?
- Wind tunnel blockage less than 5%?
- Tunnel speed monitored during testing?
- Sensors calibrated periodically against standard?
- Model scale adequate to give good measurement resolution?
- Model scale adequate to reproduce sufficient depth of approach wind boundary layer?
- Testing conducted at sufficient speeds to achieve Reynolds number independence?
- Wind tunnel flow characteristics uniform in crosswind direction?
- Regular checks of data collection procedures and repeatability?

SYMBOLS

a = exponent in power law wind speed profile, Equation (10)
A_e = stack or exhaust exit face area, ft^2
A_o = terrain roughness correction factor for wind speeds measured at standard 33-ft height, Equation (9)
B_L = larger of two upwind building face dimensions, H and W, ft
B_s = smaller of two upwind building face dimensions, H and W, ft
B_1 = air entrainment parameter in distance dilution D_s, Equation (21)
C_e = contaminant mass concentration in exhaust at exhaust temperature T_e, Equation (13), lb/ft^3
C = contaminant mass concentration at receptor at ambient air temperature T_a, lb/ft^3
C_p = local wind pressure coefficient on building surface, Equation (8)
d = $(4A_e/\pi)^{0.5}$, effective exhaust stack diameter, ft
D = C_e/C dilution factor between source and receptor mass concentrations, Equation (12)
D_{min} = minimum dilution factor D at given wind speed for all exhaust locations at same fixed distance S from intake
$D_{min,0}$ = minimum dilution factor D_{min} at roof level for flush vent with zero stack height, $h_s = 0$, Equation (19)
D_{crit} = critical dilution factor at roof level for uncapped vertical exhaust at critical wind speed U_{crit} that produces smallest value of D_{min} for given exhaust to intake distance S and stack height h_s, Equations (23), (27), and (28)

$D_{crit,0}$ = critical dilution factor D_{crit}, at roof level for uncapped vertical exhaust with stack height $h_s = 0$, Equation (23)
D_0 = apparent initial dilution factor for exhaust jet, Equation (20)
D_s = distance dilution factor at fixed wind speed, Equation (21)
D_v = dilution factor for volume fraction concentration, Equation (15)
f = volume concentration fraction at receptor; ratio of contaminant gas volume to total mixture volume, ppm $\times 10^6$
f_e = contaminant volume concentration fraction in exhaust gas; ratio of contaminant gas volume to total mixture volume, Equation (14), ppm $\times 10^{-6}$
g = acceleration of gravity, ft/s^2
H = wall height aboveground on upwind building face, Figures 2 and 14, ft
H_c = maximum height above roof level of upwind roof edge flow recirculation zone, Figure 3, ft
H_{ref} = height of wind anemometer at meteorological station, ft
h_d = downwash correction to be subtracted from stack height, Equation (24), Figure 16, ft
h_s = effective exhaust stack height above rooftop obstacles and enclosures, Figure 3, ft
h_{sc} = required height of capped exhaust stack to avoid excessive intake contamination, ft
h_r = plume rise of uncapped vertical exhaust jet, ft
K_c = normalized concentration coefficient CU_HHW/Q
L = length of building in wind direction, Figures 2 and 14, ft
L_c = length of upwind roof edge recirculation zone, Figure 3, ft
L_r = length of flow recirculation zone behind rooftop obstacle or building, Figure 3, ft
m = contaminant mass release rate, Equation (13), lb/s
M = configuration factor, Equation (18)
p_s = wind pressure difference between exterior building surface location and local outdoor atmospheric pressure at same level in undisturbed approach wind, Equation (8), lb/ft^2
p_v = velocity pressure of wind at roof level, Equation (7), lb/ft^2
Q_e = A_eV_e, total exhaust gas mixture flow rate, ft^3/s
R = scaling length for roof flow patterns, Equation (1), ft
S = stretched string distance; the shortest distance from exhaust to intake over and along building surface, Figure 3, ft
T_a = outdoor ambient air absolute temperature, °R
T_e = exhaust air mixture absolute temperature, °R
t_a = time interval over which receptor (intake) concentrations are averaged in computing dilution, Equation (16), s
U^* = ground surface friction velocity, ft/s
U_{ref} = wind speed at height of meteorological station anemometer in undisturbed wind in same terrain roughness in which building is located, Equation (9), ft/s
U_{crit} = critical wind speed that produces smallest minimum dilution factor D_{crit} for uncapped vertical exhaust at given S and h_s, Equation (27), ft/s
$U_{crit,o}$ = critical wind speed for smallest minimum dilution factor $D_{crit,o}$ for *flush uncapped exhaust with zero stack height* $h_s = 0$, Equation (22), ft/s
U_H = mean wind speed for 10-min averaging at height of upwind wall in undisturbed flow approaching building, Figure 1, ft/s
U_{met} = meteorological station wind speed, measured (or corrected to) height of $Z = 33$ ft aboveground in smooth terrain, ft/s
V_e = exhaust face velocity, Q_e/A_e, ft/s
W = width of upwind building face, Figures 2 and 14, ft
X = distance from upwind roof edge, ft
X_c = distance from upwind roof edge to H_c, Figure 17, ft
Y = $12.6(h_s/s)^2$ in Equations (25, 26)
Z = height above local ground level, ft
Z_1 = height of flow recirculation zone boundary above roof, Figure 17, ft
Z_2 = height of high turbulence zone boundary above roof, Figure 17, ft
Z_3 = height of roof edge wake boundary above the roof, Figure 17, ft
Z_o = log-law terrain roughness scaling length, Figure 4, ft
α = configuration parameter, Equation (17)
β = capping factor; $\beta = 1.0$ for vertical uncapped roof exhaust; $\beta = 0$ for capped, louvered, or downward-facing exhaust, Equation (20)
δ = fully developed strong wind atmospheric boundary layer thickness, Figure 4, ft
δ_2 = developing internal boundary layer thickness from change in terrain roughness, Figure 12, Table 1, ft
θ = wind angle between perpendicular line from the upwind building face to wind direction, Figure 6, degrees
ρ_a = density of outdoor air, lb/ft^3
ρ_e = density of exhaust gas mixture, lb/ft^3
ν = kinematic viscosity of outdoor air, ft^2/s

COMBUSTION AND FUELS

Principles of Combustion 15.1
Fuel Classification 15.3
Gaseous Fuels 15.4
Liquid Fuels 15.5
Solid Fuels 15.7
Combustion Calculations 15.8
Efficiency Calculations 15.12
Practical Combustion Considerations 15.14

PRINCIPLES OF COMBUSTION

COMBUSTION is the chemical process in which an oxidant is reacted rapidly with a fuel to liberate stored energy as thermal energy, generally in the form of high-temperature gases. Small amounts of electromagnetic energy (light), electric energy (free ions and electrons), and mechanical energy (noise) are also released during the combustion process. Except in special applications, the oxidant for combustion is oxygen in the air.

Conventional hydrocarbon fuels contain primarily hydrogen and carbon, in elemental form or in various compounds. Their complete combustion produces mainly carbon dioxide and water; however, small quantities of carbon monoxide and partially reacted flue gas constituents (gases and liquid or solid aerosols) may form. Most conventional fuels also contain small amounts of sulfur, oxidized to SO_2 or SO_3 during combustion, and noncombustible substances, *i.e.*, mineral matter (ash), water, and inert gases. Flue gas is the product of complete or incomplete combustion including excess air (if present), but not dilution air.

Fuel combustion rate depends on: (1) the chemical reaction rate of combustible fuel constituents with oxygen, (2) the rate at which oxygen is supplied to fuel (mixing of air and fuel), and (3) the temperature in the combustion region. The reaction rate is fixed by fuel selection. Increasing the mixing rate or temperature increases the combustion rate.

With *complete combustion* of hydrocarbon fuels, all hydrogen and carbon in the fuel are oxidized to H_2O and CO_2. Generally, for complete combustion, excess oxygen or excess air must be supplied beyond the amount theoretically required to oxidize the fuel; this is usually expressed as a percentage of the air required to completely oxidize the fuel.

In *stoichiometric combustion* of a hydrocarbon fuel, fuel is reacted with the exact amount of oxygen required to oxidize all carbon, hydrogen, and sulfur in the fuel to CO_2, H_2O, and SO_2. Therefore, exhaust gas from stoichiometric combustion theoretically contains no incompletely oxidized fuel constituents and no unreacted oxygen; *e.g.*, no excess air or oxygen, and no carbon monoxide. The percentage of CO_2 contained in products of stoichiometric combustion is the maximum attainable, referred to as *stoichiometric CO_2*, *ultimate CO_2*, or *maximum theoretical percentage of CO_2*.

Stoichiometric combustion is seldom realized in practice because of imperfect mixing and finite reaction rates. Consequently, for economy and safety, most combustion equipment should operate with some excess air. This ensures that fuel is not wasted and that combustion equipment is sufficiently flexible to provide complete combustion despite variations in fuel properties and in the supply rates of fuel and air. Combustion equipment is designed and operated to ensure complete, not stoichiometric, combustion. The exact amount of excess air supplied to any particular combustion equipment depends on such factors as (1) expected variations in fuel properties and in fuel and air supply rates, (2) equipment application, (3) degree of operator supervision required or available, and (4) control requirements. For maximum efficiency, combustion at low excess air is desirable.

Incomplete combustion occurs when a fuel element is not completely oxidized in the combustion process. For example, a hydrocarbon may not completely oxidize to carbon dioxide and water but may form partially oxidized compounds, such as carbon monoxide, aldehydes, and ketones. Conditions that promote incomplete combustion include (1) insufficient air and fuel mixing (causing local fuel-rich and fuel-lean zones), (2) insufficient air supply to the flame (providing less than the required quantity of oxygen), (3) insufficient reactant residence time in the flame (preventing completion of combustion reactions), (4) flame impingement on a cold surface (quenching combustion reactions), or (5) a too-low flame temperature (slowing combustion reactions).

Incomplete combustion uses fuel inefficiently, can be hazardous because of carbon monoxide production, and contributes to air pollution.

Combustion Reactions

Combustion of oxygen with the combustible elements and compounds in fuels occurs according to fixed chemical principles, including:

- Chemical reaction equations.
- Law of matter conservation. The mass of each element in the reaction products must equal the mass of that element in the reactants.
- Law of combining weights. Chemical compounds are formed by elements combining in fixed weight relationships.
- Chemical reaction rates.

Oxygen for combustion is normally obtained from air, a physical mixture of nitrogen, oxygen, small amounts of water vapor, carbon dioxide, and inert gases. For practical combustion calculations, dry air consists of 20.95% oxygen and 79.05% inert gases (nitrogen, argon, and so forth) by volume, or 23.15% oxygen and 76.85% inert gases by weight. For calculation purposes, nitrogen is assumed to pass through the combustion process unchanged (although small quantities of nitrogen oxides are known to form). Table 1 lists oxygen and air requirements for stoichiometric combustion of some pure combustible materials (or constituents) found in common fuels. Table 2 lists the products of combustion for stoichiometric combustion of the same pure combustible materials.

Flammability Limits

Fuel will burn in a self-sustained reaction only when the volume percentages of fuel and air in a mixture at standard temperature and pressure are within specific limits: the upper and lower flammability limits or explosive limits (UEL and LEL). Both temperature and pressure affect these limits. As the temperature of the mixture increases, the upper limit increases and the lower limit decreases. As the pressure of the mixture decreases below atmospheric pressure, the upper limit decreases and the lower limit

The preparation of this chapter is assigned to TC 3.7, Fuels and Combustion.

Table 1 Combustion Reactions of Common Fuel Constituents

Constituent	Molecular Symbol	Combustion Reactions	Stoichiometric Oxygen and Air Requirements			
			lb/lb Fuel[a]		ft^3/ft^3 Fuel	
			O_2	Air	O_2	Air
Carbon (to CO)	C	$C + 0.5\alpha_2 \rightarrow CO$	1.33	5.75	—	—
Carbon (to CO_2)	C	$C + O_2 \rightarrow CO_2$	2.66	11.51	—	—
Carbon monoxide	CO	$CO + 0.5\alpha_2 \rightarrow CO_2$	0.57	2.47	0.50	2.39
Hydrogen	H_2	$H_2 + 0.5\alpha_2 \rightarrow H_2O$	7.94	34.28	0.50	2.39
Methane	CH_4	$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$	3.99	17.24	2.00	9.57
Ethane	C_2H_6	$C_2H_6 + 3.5O_2 \rightarrow 2CO_2 + 3H_2O$	3.72	16.09	3.50	16.75
Propane	C_3H_8	$C_3H_8 + 5O_2 \rightarrow 3CO_2 + 4H_2O$	3.63	15.68	5.00	23.95
Butane	C_4H_{10}	$C_4H_{10} + 6.5O_2 \rightarrow 4CO_2 + 5H_2O$	3.58	15.47	6.50	31.14
—	C_nH_{2n+2}	$C_nH_{2n+2} + (1.5n + 0.5)O_2 \rightarrow nCO_2 + (n+1)H_2O$	—	—	$1.5n + 0.5$	$7.18n + 2.39$
Ethylene	C_2H_4	$C_2H_4 + 3O_2 \rightarrow 2CO_2 + 2H_2O$	3.42	14.78	3.00	14.38
Propylene	C_3H_6	$C_3H_6 + 4.5O_2 \rightarrow 3CO_2 + 3H_2O$	3.42	14.78	4.50	21.53
—	C_nH_{2n}	$C_nH_{2n} + 1.5nO_2 \rightarrow nCO_2 + nH_2O$	3.42	14.78	$1.50n$	$7.18n$
Acetylene	C_2H_2	$C_2H_2 + 2.5\alpha_2 \rightarrow 2CO_2 + H_2O$	3.07	13.27	2.50	11.96
—	C_nH_{2m}	$C_nH_{2m} + (n + 0.5m)O_2 \rightarrow nCO_2 + mH_2O$	—	—	$n + 0.5m$	$4.78n + 2.39m$
Sulfur (to SO_2)	S	$S + O_2 \rightarrow SO_2$	1.00	4.31	—	—
Sulfur (to SO_3)	S	$S + 1.5O_2 \rightarrow SO_3$	1.50	6.47	—	—
Hydrogen sulfide	H_2S	$H_2S + 1.5O_2 \rightarrow SO_2 + H_2O$	1.41	6.08	1.50	7.18

[a] Atomic masses: H = 1.008; C = 12.01; O = 16.00; S = 32.06.

increases. However, as pressure increases above atmospheric pressure, the upper limit increases and the lower limit is relatively constant (see Table 3).

Ignition Temperature

Ignition temperature is the lowest temperature at which heat is generated by combustion faster than heat is lost to the surroundings and combustion becomes self-propagating. The fuel-air mixture will not burn freely and continuously below the ignition temperature unless heat is supplied, but chemical reaction between the fuel and air may occur. Ignition temperature is affected by a large number of factors in varying degrees.

The ignition temperature and flammability limits of a fuel-air mixture, together, are a measure of the potential for ignition (*Gas Engineers Handbook* 1965).

Combustion Modes

Combustion reactions occur in either continuous or pulse flame modes. *Continuous combustion* burns fuel in a sustained manner as long as fuel and air are continuously fed to the combustion zone and the fuel-air mixture is within the flammability limits. Continuous combustion is more common than pulse combustion and is used in most fuel-burning equipment.

Pulse combustion is an acoustically resonant process that burns various fuels in small, discrete fuel-air mixture volumes in a very rapid series of combustions.

The introduction of fuel and air into the pulse combustor is controlled by mechanical or aerodynamic valves. Typical combustors consist of one or more valves, a combustion chamber, an exit pipe, and a control system (ignition means, fuel metering devices, etc.). Typically, warm air furnace, hot water boiler, and commercial cooking equipment combustors use mechanical valves. Aerodynamic valves are usually used in higher pressure applications, such as thrust engines. Separate valves for air and fuel, a single valve for premixed air and fuel, or multiple valves of either type can be used. Premix valve systems may require a flame trap at the combustion chamber entrance to prevent flashback.

In a mechanically valved pulse combustor, air and fuel are forced into the combustion chamber through the valves under less than 0.5 psi pressure. An ignition source, such as a spark, ignites the fuel-air mixture, causing a positive pressure build-up in the combustion chamber. The positive pressure causes the valves to close, leaving only the exit pipe of the combustion chamber as a pressure relief opening. The combustion chamber and exit pipe geometry determine the resonant frequency of the combustor. The pressure wave from the initial combustion travels down the exit pipe at sonic velocity. As this wave exits the combustion chamber, most of the flue gases present in the chamber will be carried with it into the exit pipe. Flue gases remaining in the combustion chamber immediately begin to cool. The contraction of the cooling gases and the momentum of gases in the exit pipe create a vacuum inside the chamber that opens the valves and allows more fuel and air into the chamber. While the fresh charge of fuel-air enters the chamber, the pressure wave reaches the end of the exit pipe and is partially reflected from the open end of the pipe. The fresh fuel-air charge is ignited by residual combustion and/or heat. The resulting combustion starts another cycle.

Typical pulse combustors operate at 30 to 100 cycles per second and emit resonant sound, which must be considered in their application. Pulse combustion produces heat, as does any other combustion process. The pulses produce high convective heat transfer rates.

Heating Values

Combustion releases thermal energy or heat. The quantity of heat generated by complete combustion of a unit of specific fuel is constant and is termed the *heating value, heat of combustion*, or *caloric value* of that fuel. The heating value of a fuel can be determined by measuring the heat evolved during combustion of a known quantity of the fuel in a calorimeter, or it can be estimated from chemical analysis of the fuel and the heating value of the various chemical elements in the fuel.

Higher heating value, gross heating value, or *total heating value* is determined when water vapor in fuel combustion products is condensed and the latent heat of vaporization is included in the fuel's heating value. Conversely, *lower heating value* or *net heating value* is obtained when latent heat of vaporization is not included. When the heating value of a fuel is specified without designating higher or lower, it generally means the higher heating value in the United States. (Lower heating value is mainly used for internal combustion engine fuels.)

Heating values are usually expressed in Btu/ft^3 for gaseous fuels, Btu/gal for liquid fuels, and Btu/lb for solid fuels. Heating values are always given in relation to a certain reference temperature and pressure, usually 60, 68, or 77 °F and 14.696 psia, depending on the particular industry practice. Heating values of several substances in common fuels are listed in Table 4.

Table 2 Combustion Reactions of Common Fuel Constituents

Constituent	Molecular Symbol	Flue Gas from Stoichiometric Combustion: Ultimate CO_2, %	Dew Point, °F	Unit Volume: Unit Volume of Fuel CO_2	Unit Volume: Unit Volume of Fuel H_2O	Unit Mass: Unit Mass of Fuel CO_2	Unit Mass: Unit Mass of Fuel H_2O

Acetylene	C_2H_2	2.50	81	763 to 824	Trinks (1947)
Sulfur	S	—	—	374	Hartman (1958)
Hydrogen sulfide	H_2S	4.3	45.50	558	Scott *et al.* (1948)

Flammability limits adapted from Coward and Jones (1952). All values corrected to 60°F, 30 in. Hg, dry.

With incomplete combustion, not all fuel is completely oxidized, and the heat released is less than the heating value of the fuel. Therefore, the quantity of heat produced per unit of fuel consumed decreases, implying lower combustion efficiency.

Not all heat released during combustion can be used effectively. The greatest heat loss is in the form of increased temperature (thermal energy) of hot exhaust gases above the temperature of incoming air and fuel. Other heat losses include radiation and convection heat transfer from the outer walls of combustion equipment to the environment.

Altitude Compensation

Air at altitudes above sea level has less density and, therefore, less oxygen per unit volume. Combustion at altitudes above sea level will have less available oxygen to burn with fuel unless compensation is made for the altitude. Combustion will occur, but the excess air will be reduced. If excess air is reduced excessively by an increase in altitude, combustion will be incomplete or cease.

Altitude compensation is achieved by matching the fuel and air supply rates to attain complete combustion without too much excess air or too much fuel. Fuel and air supply rates can be matched by increasing the air supply rate to the combustion zone or by decreasing the fuel supply rate to the combustion zone. The air supply rate can be increased with a combustion air blower, and the fuel supply rate can be reduced by decreasing the fuel input (derating).

Power burners use combustion air blowers and can increase the air supply rate to compensate for altitude. The combustion zone can be pressurized to attain the same air density in the combustion chamber as that attained at sea level.

Derating can be used as an alternative to power combustion. In the United States, the fuel gas codes generally do not require derating of nonpower burners at altitudes up to 2000 ft. At altitudes above 2000 ft, burners should be derated 4% for each 1000 ft above sea level (NFPA and AGA 1992). Chimney or vent operation also must be considered at high altitudes (see Chapter 31 of the 1992 ASHRAE *Handbook—Systems and Equipment*).

FUEL CLASSIFICATION

Generally, hydrocarbon fuels are classified according to physical state (gaseous, liquid, or solid). Different types of combustion

Table 4 Heating Values of Substances Occurring in Common Fuels

Substance	Molecular Symbol	Higher Heating Values[a], Btu/lb	Lower Heating Values[a], Btu/lb	Specific Volume[b], ft^3/lb
Carbon (to CO)	C	3950	3950	—
Carbon (to CO_2)	C	14,093	14,093	—
Carbon monoxide	CO	4347	4347	13.5
Hydrogen	H_2	61,095	51,623	188.0
Methane	CH_4	23,875	21,495	23.6
Ethane	C_2H_6	22,323	20,418	12.5
Propane	C_3H_8	21,669	19,937	8.36
Butane	C_4H_{10}	21,321	19,678	6.32
Ethylene	C_2H_4	21,636	20,275	—
Propylene	C_3H_6	21,048	19,687	9.01
Acetylene	C_2H_2	21,502	20,769	14.3
Sulfur (to SO_2)	S	3980	3980	—
Sulfur (to SO_3)	S	5940	5940	—
Hydrogen sulfide	H_2S	7097	6537	11.0

Adapted from *Gas Engineers Handbook* (1965).
[a] All values corrected to 60 °F, 30 in. Hg, dry. For gases saturated with water vapor at 60 °F, deduct 1.74% of the value to adjust for gas volume displaced by water vapor.
[b] At 32 °F and 29.92 in. Hg.

equipment are usually needed to burn fuels in different physical states. Gaseous fuels can be burned in premix or diffusion burners that take advantage of the gaseous state. Liquid fuel burners must include a means for atomizing or vaporizing fuel into small droplets or a vapor for burning and must provide adequate mixing of fuel and air. Finally, solid fuel combustion equipment must (1) heat fuel to vaporize sufficient volatiles to initiate and sustain combustion, (2) provide residence time to complete combustion, and (3) provide space for ash containment.

Principal fuel applications include space heating and cooling of residential, commercial, industrial, and institutional buildings; service water heating; steam generation; and refrigeration. Major fuels for these applications are natural and liquefied petroleum gases, fuel oils, diesel and gas turbine fuels (for total energy applications), and coal.

Fuels of limited use, such as manufactured gases, kerosene, briquettes, wood, and coke, are not discussed here. Fuel choice is based on one or more of the following:

1. Fuel factors
   - Availability, including dependability of supply
   - Convenience of use and storage
   - Economy
   - Cleanliness
2. Combustion equipment factors
   - Operating requirements
   - Cost
   - Service requirements
   - Ease of control

GASEOUS FUELS

Although various gaseous fuels have been used as energy sources in the past, heating and cooling applications are presently limited to natural and liquefied petroleum gases.

Types and Properties

Natural gas is a nearly odorless and colorless gas that accumulates in the upper parts of oil and gas wells. Raw natural gas is a mixture of methane (55 to 98%), higher hydrocarbons (primarily ethane), and noncombustible gases. Some constituents, principally water vapor, hydrogen sulfide, helium, liquefied petroleum gases, and gasoline are removed prior to distribution.

Table 5 Propane-Air and Butane-Air Gas Mixtures

	Propane-Air[a]			Butane-Air[b]		
Btu/ft^3	%Gas	%Air	Sp Gr	%Gas	%Air	Sp Gr
500	19.8	80.2	1.103	15.3	84.7	1.155
600	23.8	76.2	1.124	18.4	81.6	1.186
700	27.8	72.2	1.144	21.5	78.5	1.216
800	31.7	68.3	1.165	24.5	75.5	1.248
900	35.7	64.3	1.185	27.6	72.4	1.278
1000	39.7	60.3	1.206	30.7	69.3	1.310
1100	43.6	56.4	1.227	33.7	66.3	1.341
1200	47.5	52.5	1.248	36.8	63.2	1.372
1300	51.5	48.5	1.268	39.8	60.2	1.402
1400	55.5	44.5	1.288	42.9	57.1	1.433
1500	59.4	40.6	1.309	46.0	54.0	1.464
1600	63.4	36.6	1.330	49.0	51.0	1.495
1700	67.4	32.6	1.350	52.1	47.9	1.526
1800	71.3	28.7	1.371	55.2	44.8	1.557

Adapted from *Gas Engineers Handbook* (1965).
[a] Values used for calculation: 2522 Btu/ft^3; 1.52 specific gravity.
[b] Values used for calculation: 3261 Btu/ft^3; 2.01 specific gravity.

Typical compositions of natural gas used as fuel include: methane, CH_4 (70 to 96%); ethane, C_2H_6 (1 to 14%); propane, C_3H_8 (0 to 4%); butane, C_4H_{10} (0 to 2%); pentane, C_5H_{12} (0 to 0.5%); hexane, C_6H_{14} (0 to 2%); carbon dioxide, CO_2 (0 to 2%); oxygen, O_2 (0 to 1.2%); and nitrogen, N_2 (0.4 to 17%).

The composition of a natural gas depends on its geographical source. The composition of gas distributed in a given location can vary slightly since the gas is drawn from various sources, but a fairly constant heating value is usually maintained for control and safety. Local gas utilities are the best sources of current gas composition data for a particular area.

Heating values of natural gases vary from 900 to 1200 Btu/ft^3; the usual range is 1000 to 1050 Btu/ft^3 at sea level. Unknown heating values for particular gases can be calculated from composition data and Table 4.

For safety purposes, odorants (such as mercaptans) are added to natural gas and LPG to give them noticeable odors.

Liquefied petroleum gases (LPG) consist primarily of propane and butane, usually obtained as a byproduct of oil refinery operations or by stripping natural gas. Propane and butane are gaseous under usual atmospheric conditions, but can be liquefied by moderate pressures at normal temperatures.

Three liquefied petroleum gases—butane, propane, and a mixture of the two—are commercially available as fuels.

Commercial propane consists primarily of propane but generally contains about 5 to 10% propylene. It has a heating value of about 21,560 Btu/lb or about 2500 Btu/ft^3 of gas. At atmospheric pressure, commercial propane has a boiling point of about −40 °F. The low boiling point of propane makes it usable during winter in the northern United States and in Canada. Tank heaters and vaporizers permit its use in colder climates and where high fuel flow rates are required. It is available in cylinders, bottles, tank trucks, or tank cars.

Commercial butane consists primarily of butane but may contain up to 5% butylene. It has a heating value of about 21,180 Btu/lb or about 3200 Btu/ft^3. At atmospheric pressure, commercial butane has a relatively high boiling point of about 32 °F. Therefore, butane cannot be used in cold weather unless the gas temperature is maintained above 32 °F or butane partial pressure is decreased by dilution with lower boiling point gases. Butane is usually available in bottles, tank trucks, or tank cars, but not in cylinders.

Commercial propane-butane mixtures with varying ratios of propane and butane are available. Their properties generally fall between those of the unmixed fuels. Propane-air and butane-air mixtures are used in place of natural gas in small communities

and by natural gas companies at peak loads. Table 5 lists heating values and specific gravities for various fuel-air ratios.

Manufactured gases are combustible gases produced from coal, coke, oil, liquefied petroleum gases, or natural gas. For more detailed information, see *Gas Engineers Handbook* (1965). These fuels are used primarily for industrial in-plant operations or as specialty fuels (*e.g.*, acetylene for welding).

LIQUID FUELS

Significant liquid fuels include various fuel oils for firing combustion equipment and engine fuels for total energy systems. Liquid fuels, with few exceptions, are mixtures of hydrocarbons derived by refining crude petroleum. In addition to hydrocarbons, crude petroleum usually contains small quantities of sulfur, oxygen, nitrogen, vanadium, other trace metals, and impurities such as water and sediment. Refining produces a variety of fuels and other products. Nearly all lighter hydrocarbons are refined into fuels (*e.g.*, liquefied petroleum gases, gasoline, kerosene, jet fuels, diesel fuels, and light heating oils). Heavy hydrocarbons are refined into residual fuel oils and other products (*e.g.*, lubricating oils, waxes, petroleum coke, and asphalt).

Crude petroleums from different oil fields vary in hydrocarbon molecular structure. Crude is paraffin-base (principally chain-structured paraffin hydrocarbons), naphthene- or asphaltic-base (containing relatively large quantities of saturated ring-structural naphthenes), aromatic-base (containing relatively large quantities of unsaturated, ring-structural aromatics), or mixed- or intermediate-base (between paraffin- and naphthene-base crudes). Except for heavy fuel oils, crude type has little significant effect on resultant products and combustion applications.

Types of Fuel Oils

Fuel oils for heating are broadly classified as *distillate* fuel oils (lighter oils) or *residual* fuel oils (heavier oils). ASTM has established specifications for fuel oil properties which subdivide the oils into various grades. Grades No. 1 and 2 are distillate fuel oils. Grades 4, 5 (Light), 5 (Heavy), and 6 are residual fuel oils. Specifications for the grades are based on required characteristics of fuel oils for use in different types of burners. The ANSI standard specification for fuel oils is ASTM *Standard* D396-86.

Grade No. 1 is a light distillate intended for vaporizing-type burners. High volatility is essential to continued evaporation of the fuel oil with minimum residue.

Grade No. 2 is a heavier (API Gravity) distillate than No. 1. It is used primarily with pressure-atomizing (gun) burners that spray the oil into a combustion chamber. The atomized oil vapor mixes with air and burns. This grade is used in most domestic burners and many medium capacity commercial-industrial burners.

Grade No. 4 is an intermediate fuel that is considered either a light residual or a heavy distillate. Intended for burners that atomize oils of higher viscosity than domestic burners can handle, its permissible viscosity range allows it to be pumped and atomized at relatively low storage temperatures. A dewaxed No. 2 oil with a pour point of −58 °F is supplied only to areas where regular No. 2 oil would jell.

Grade No. 5 (Light) is a residual fuel of intermediate viscosity for burners that handle fuel more viscous than No. 4 without preheating. Preheating may be necessary in some equipment for burning and, in colder climates, for handling.

Grade No. 5 (Heavy) is a residual fuel more viscous than No. 5 (Light), but intended for similar purposes. Preheating is usually necessary for burning and, in colder climates, for handling.

Grade No. 6, sometimes referred to as Bunker C, is a high viscosity oil used mostly in commercial and industrial heating. It requires preheating in the storage tank to permit pumping, and additional preheating at the burner to permit atomizing.

Low sulfur residual oils are marketed in many areas to permit users to meet sulfur dioxide emission regulations. These fuel oils are produced (1) by refinery processes that remove sulfur from the oil (hydrodesulfurization), (2) by blending high sulfur residual oils with low sulfur distillate oils, or (3) by a combination of these methods. These oils have significantly different characteristics than regular residual oils. For example, the viscosity-temperature relationship can be such that low sulfur fuel oils have viscosities of No. 6 fuel oils when cold, and of No. 4 when heated. Therefore, normal guidelines for fuel handling and burning can be altered when using these fuels.

Fuel oil grade selection for a particular application is usually based on availability and economic factors, including fuel cost, clean air requirements, preheating and handling costs, and equipment cost. Installations with low firing rates and low annual fuel consumption cannot justify the cost of preheating and other methods that use residual fuel oils. Large installations with high annual fuel consumption cannot justify the premium cost of distillate fuel oils. Disagreements on economy occur somewhere in between.

Characteristics of Fuel Oils

Characteristics that determine grade classification and suitability for given applications are: (1) flash point, (2) viscosity, (3) pour point, (4) water and sediment content, (5) carbon residue, (6) ash, (7) distillation qualities, (8) specific gravity, (9) sulfur, (10) carbon-hydrogen content, and (11) heating value. Not all of these are included in ASTM *Standard* D396-86.

Viscosity is an oil's resistance to flow. It is significant because it indicates the ease at which oil will flow or be pumped and the ease of atomization. Approximate viscosities of fuel oils are shown in Figure 1.

Flash point is the maximum temperature at which an oil can be stored and handled. Minimum permissible flash point is usually prescribed by state and municipal laws.

Pour point is the lowest temperature at which a fuel can be stored and handled. Higher pour point fuels can be used when heated storage and piping facilities are provided.

Water and *sediment* should be low to prevent fouling the facilities. Sediment accumulates on filter screens and burner parts. Water in distillate fuels can cause tanks to corrode and emulsions to form in residual oil.

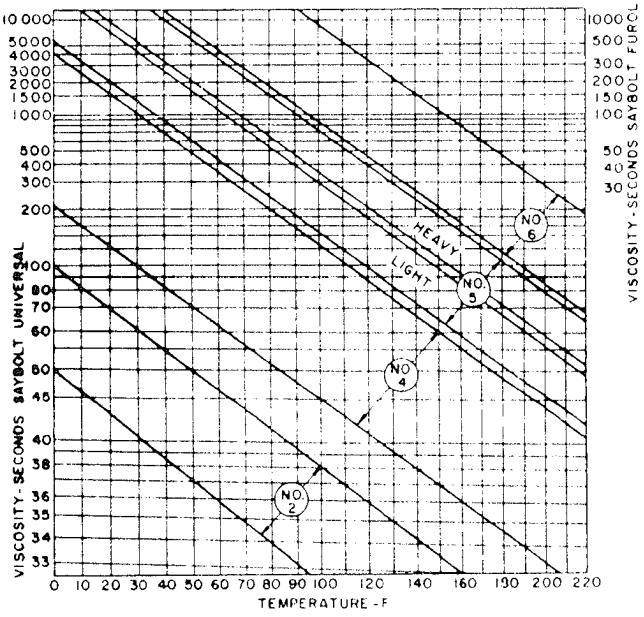

Fig. 1 Approximate Viscosity of Fuel Oils

Carbon residue is obtained by a test in which the oil sample is destructively distilled in the absence of air. When commercial fuels are used in proper burners, this residue has almost no relationship to soot deposits, except indirectly when deposits are formed by vaporizing burners.

Ash is the noncombustible material in an oil. An excessive amount indicates the presence of materials that cause high wear on burner pumps.

The *distillation* test shows the volatility and ease of vaporization of a fuel.

Specific gravity is the ratio of a fuel oil density to the density of water at a specific temperature. Differences in fuel oil viscosities are caused by variations in the concentrations of fuel oil constituents and different refining methods. Specific gravities cover a range in each grade, with some overlap between distillate and residual grades. API gravity, a parameter widely used in place of specific gravity, is obtained by the following formula, in which specific gravity at 60/60 °F indicates the ratio of the mass of a given volume of oil at 60 °F to the same volume of water at 60 °F:

$$\text{deg API} = \frac{141.5}{\text{Sp Gr at } 60/60\,^{\circ}\text{F}} - 131.5 \qquad (1)$$

The API gravity of water at 60 °F is 10.0.

Air pollution considerations are important in determining the allowable sulfur content of fuel oils. Sulfur content is frequently limited by legislation aimed at reducing sulfur oxide emissions from combustion equipment. These laws require sulfur content to be below a certain level, usually 1.0, 0.5, or 0.3%.

Sulfur in fuel oils is also undesirable because of the corrosiveness of sulfur compounds in the flue gas. While low-temperature corrosion can be minimized by maintaining the stack at temperatures above the dew point of the flue gas, this limits the overall thermal efficiency of combustion equipment.

For certain industrial applications, the sulfur content of a fuel must be limited because of adverse effects on product quality. These include direct-fired metallurgical applications where work is in the combustion zone.

Table 6 lists the sulfur levels of some marketed fuel oils.

Heating value is an important property, although ASTM *Standard* D396-86 does not list it as one of the criteria for fuel oil classification. Heating value can generally be correlated with the API gravity. Table 7 shows the relationship between heating value, API gravity, and density for several oil grades. In the absence of more specific data, heating values can be calculated as shown in the *North American Combustion Handbook* (1965):

$$\text{Higher Heating Value, Btu/lb} = 22{,}320 - 3780\,(\text{Specific Gravity})^2 \qquad (2)$$

Distillate fuel oils (Grades 1 and 2) have a carbon-hydrogen content of 84 to 86% carbon, with the remainder predominantly hydrogen. The heavier grades (4, 5, and 6) may contain up to 88% carbon and as little as 11% hydrogen. An approximate relationship for determining the hydrogen content of fuel oils is:

$$\text{Hydrogen, \%} = 26 - (15 \times \text{Specific Gravity}) \qquad (3)$$

ASTM *Standard* D396-86 is more a classification than a specification, distinguishing between six generally nonoverlapping grades, one of which characterizes any commercial fuel oil. Quality is not defined, as a refiner might control it; for example, the standard lists the distillation temperature 90% point for Grade No. 2 as having a maximum of 640 °F, whereas commercial practice rarely exceeds 600 °F.

Table 6 Sulfur Content of Marketed Fuel Oils

Grade of Oil	No. 1	No. 2	No. 4	No. 5 (Light)	No. 5 (Heavy)	No. 6
Total fuel samples	123	158	13	15	16	96
Sulfur content,						
% Wt. Min.	0.002	0.03	0.46	0.90	0.57	0.32
Max.	0.380	0.64	1.44	3.50	2.92	4.00
No. samples with S						
over 0.3%	1	32	13	15	16	96
over 0.5%	0	1	11	15	16	93

over 3.0%	0	0	0	2	0	8

Derived from *Burner Oil Fuels* (1974).

Table 7 Typical Gravity and Heating Value of Standard Grades of Fuel Oil

Grade No.	Gravity API	Density, lb/gal	Heating Value, Btu/gal
1	38 to 45	6.950 to 6.675	137,000 to 132,900
2	30 to 38	7.296 to 6.960	141,800 to 137,000
4	20 to 28	7.787 to 7.396	148,100 to 143,100
5L	17 to 22	7.940 to 7.686	150,000 to 146,800
5H	14 to 18	8.080 to 7.890	152,000 to 149,400
6	8 to 15	8.448 to 8.053	155,900 to 151,300

Types and Properties of Liquid Fuels for Engines

The primary stationary engine fuels are diesel and gas turbine oils, natural gases, and liquefied petroleum gases. Other fuels include sewage gas, manufactured gas, and gas mixtures. Gasoline and the JP series of gas turbine fuels are rarely used for stationary engines.

Only properties of diesel and gas turbine fuel oils are covered here; properties of natural and liquefied petroleum gases are found in the section Gaseous Fuels. For properties of gasolines and JP turbine fuel, consult texts on internal combustion engines and gas turbines (Bibliography). Properties of currently marketed gasolines can be found in the latest volumes of *Mineral Industry Surveys, Motor Gasolines*, issued semiannually by the Bureau of Mines.

Properties of the three grades of diesel fuel oils are listed in ASTM *Specification* D975.

Grade No. 1-D includes the class of volatile fuel oils from kerosene to intermediate distillates. These fuels are used in high-speed engines with frequent and relatively wide variations in loads and speeds and where abnormally low fuel temperatures are encountered.

Grade No. 2-D includes the class of lower volatility distillate gas oils. These fuels are used in high-speed engines with relatively high loads and uniform speeds, or in engines not requiring fuels with the higher volatility or other properties specified for Grade No. 1-D.

Grade No. 4-D covers the class of more viscous distillates and blends of these distillates with residual fuel oils. These fuels are used in low- and medium-speed engines involving sustained loads at essentially constant speed.

Property specifications and test methods for No. 1-D, 2-D, and 4-D diesel fuel oils are essentially identical to specifications of No. 1, 2, and 4 fuel oils, respectively. However, diesel fuel oils have an additional specification for cetane number, which measures ignition quality and influences combustion roughness. Cetane number requirements depend on engine design, size, speed and load variations, and starting and atmospheric conditions. The increase in cetane number over values actually required does not materially improve engine performance. Thus, the cetane number should be as low as possible to assure maximum fuel availability. ASTM *Standard* D975 states several methods for estimating cetane number from other fuel oil properties.

ASTM *Specification* D2880 for gas turbine fuel oils relates gas turbine fuel oil grades to fuel and diesel fuel oil grades. Test methods for determining properties of gas turbine fuel oils are essentially identical to those for fuel oils. However, gas turbine specifications contain quantity limits on some trace elements that may be present. These limits are intended to prevent excessive corrosion in gas turbine engines. For a detailed discussion of fuels for gas turbines and combustion in gas turbines, see Chapters 5 and 9, respectively (Hazard 1971).

SOLID FUELS

Solid fuels include coal, coke, wood, and waste products of industrial and agricultural operations. Of these, only coal is widely used for heating and cooling applications.

The complex composition of coal makes classification difficult. Chemically, coal consists of carbon, hydrogen, oxygen, nitrogen, sulfur, and a mineral residue, ash. Chemical analysis provides some indication of coal quality, but does not define its burning characteristics sufficiently. The coal user is principally interested in the available heat per unit mass of coal and the amount of ash and dust produced, but is also interested in handling and storing properties and burning characteristics. A description of coal qualities and their characteristics can be obtained from the U.S. Bureau of Mines.

Types of Coals

Commonly accepted definitions for classifying coals are listed in Table 8. However, this classification is arbitrary, since there are no distinct demarcation lines between coal types.

Anthracite is a clean, dense, hard coal that creates little dust in handling. It is comparatively hard to ignite, burning freely once started. It is noncaking and burns uniformly and smokelessly with a short flame.

Semianthracite has a higher volatile content than anthracite. It is not as hard and ignites more easily. Otherwise, its properties are similar to those of anthracite.

Bituminous coal includes many types of coal with distinctly different compositions, properties, and burning characteristics. Coals range from high-grade bituminous of the East to low-rank coals of the West. Caking properties range from coals that melt or become fully plastic, to those from which volatiles and tars are distilled without changing form (classed as noncaking or free-burning). Most bituminous coals are strong and nonfriable enough to permit screened sizes to be delivered free of fines. Generally, they ignite easily and burn freely. Flame length is long and varies with different coals. If improperly fired, much smoke and soot are possible, especially at low burning rates.

Semibituminous coal is soft and friable, and handling creates fines and dust. It ignites slowly and burns with a medium flame length. Its caking properties increase as volatile matter increases, but the coke formed is weak. With only half the volatile matter content of bituminous coals, burning produces less smoke; hence, it is sometimes called smokeless coal.

Subbituminous coals, found in the West, are high in moisture when mined and tend to break up as they dry or are exposed to the weather; they are likely to ignite spontaneously when piled or stored. They ignite easily and quickly, have a medium-length flame, and are noncaking and free-burning. The lumps tend to break into small pieces if poked. Very little smoke and soot are formed.

Lignite is woody in structure, very high in moisture when mined, of low heating value, and clean to handle. It has a greater tendency than subbituminous coals to disintegrate as it dries and is also more liable to ignite spontaneously. Because of its high moisture, freshly mined lignite ignites slowly and is noncaking. The char left after moisture and volatile matter are driven off burns very easily, like charcoal. The lumps tend to break up in the fuel bed and pieces of char that fall into the ashpit continue to burn. Very little smoke or soot forms.

Table 8 Classification of Coals by Rank[a]

Class	Group	Limits of Fixed Carbon or Energy Content, Mineral-Matter-Free Basis	Requisite Physical Properties
I Anthracite	1. Metaanthracite	Dry FC, 98% or more (Dry VM, 2% or less)	Nonagglomerating
	2. Anthracite	Dry FC, 92% or more, and less than 98% (Dry VM, 8% or less, and more than 2%)	
	3. Semianthracite	Dry FC, 86% or more, and less than 92% (Dry VM, 14% or less, and more than 8%)	
II Bituminous[d]	1. Low-volatile bituminous coal	Dry FC, 78% or more, and less than 86% (Dry VM, 22% or less, and more than 14%)	Either agglomerating[b] or nonweathering[f]
	2. Medium-volatile bituminous coal	Dry FC, 69% or more, and less than 78% (Dry VM, 31% or less, and more than 22%)	
	3. High-volatile *A* bituminous coal	Dry FC, less than 69% (Dry VM, more than 31%), and moist[c], about 14,000 Btu[c] or more	
	4. High-volatile *B* bituminous coal	Moist[c], about 13,000 Btu or more, and less than 14,000[c]	
	5. High-volatile *C* bituminous coal	Moist, about 11,000 Btu or more, and less than 13,000[c]	
III Subbituminous	1. Subbituminous *A* coal	Moist, about 11,000 Btu or more, and less than 13,000[c]	Both weathering and nonagglomerating[b]
	2. Subbituminous *B* coal	Moist, about 9500 Btu or more, and less than 11,000[c]	
	3. Subbituminous *C* coal	Moist, about 8300 Btu or more, and less than 95000[c]	
IV Lignitic	1. Lignite	Moist, less than 8300 Btu	Consolidated
	2. Brown coal	Moist, less than 8300 Btu	Unconsolidated

Adapted from ASTM *Standard* D388 Rev A-91, Standard Classification of Coals by Rank.

Legend: FC = Fixed Carbon; VM = Volatile Matter.

[a] This classification does not include a few coals of unusual physical and chemical properties which come within the limits of fixed carbon or Btu of high-volatile bituminous and subbituminous ranks. All these coals either contain less than 48% dry, mineral-matter-free fixed carbon, or have more than about 15,500 moist, mineral-matter-free Btu.

[b] If agglomerating, classify in low-volatile group of the bituminous class.

[c] Moist (Btu) refers to coal containing its natural bed moisture but not including visible water on the coal surface.

[d] There may be noncaking varieties in each group of the bituminous class.

[e] Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of Btu.

[f] There are three varieties of coal in the high-volatile *C* bituminous coal group: Variety 1, agglomerating and nonweathering; Variety 2, agglomerating and weathering; Variety 3, nonagglomerating and nonweathering.

Characteristics of Coals

The characteristics of coals that determine classification and suitability for given applications are the proportions of (1) volatile matter, (2) fixed carbon, (3) moisture, (4) sulfur, and (5) ash. Each of these is reported in the proximate analysis. Coal analyses can be reported on several bases: as-received, moisture-free (dry) or dry, and mineral-matter-free (or ash-free). As-received is applicable for combustion calculations; dry and mineral-matter-free, for classification purposes.

Volatile matter is driven off as gas or vapor when the coal is heated according to a standardized temperature test. It consists of a variety of organic gases, generally resulting from distillation and decomposition. Volatile products given off by coals when heated differ materially in the ratios by weight of the gases to oils and tars. No heavy oils or tars are given off by anthracite, and very small quantities are given off by semianthracite. As volatile matter in the coal increases to as much as 40% of the coal (dry and ash-free basis), increasing amounts of oils and tars are released. However, for coals of higher volatile content, the quantity of oils and tars decreases and is relatively low in subbituminous coals and in lignite.

Fixed carbon is the combustible residue left after the volatile matter is driven off. It is not all carbon. Its form and hardness are an indication of fuel coking properties and, therefore, guide the choice of combustion equipment. Generally, fixed carbon represents that portion of fuel that must be burned in the solid state.

Moisture is difficult to determine accurately because a sample can lose moisture on exposure to the atmosphere, particularly when reducing the sample size for analysis. To correct for this loss, total moisture content of a sample is customarily determined by adding the moisture loss obtained when air-drying the sample and the measured moisture content of the dried sample. Moisture does not represent all of the water present in coal; water of decomposition (combined water) and of hydration are not given off under standardized test conditions.

Ash is the noncombustible residue remaining after complete coal combustion. Generally, the weight of ash is slightly less than that of mineral matter before burning.

Sulfur is an undesirable constituent in coal, since the sulfur oxides formed when it burns contribute to air pollution and cause combustion system corrosion. Table 9 lists the sulfur content of typical coals. Legislation has limited the sulfur content of coals burned in certain locations.

Heating values may be reported on an as-received, dry, dry and mineral-matter-free, or moist and mineral-matter-free basis. Higher heating values of coals are frequently reported with their proximate analysis. When more specific data are lacking, the higher heating value of higher quality coals can be calculated by the Dulong formula:

$$\text{Higher Heating Value, Btu/lb} = 14{,}544C + 62{,}028[H - (O/8)] + 4050S \quad (4)$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur in the coal.

Other important parameters in judging coal suitability include: (1) ultimate analysis, (2) ash-fusion temperature, (3) grindability, and (4) free-swelling index.

Ultimate analysis is another method of reporting coal composition.

Percentages of C, H, O, N, S, and ash in the coal sample are reported. Ultimate analysis is used for detailed fuel studies and for computing a heat balance when required in heating device testing. Typical ultimate analyses of various coals are shown in Table 9.

Ash-fusion temperature indicates the fluidity of the ash at elevated temperatures. It is helpful in selecting coal to be burned in a particular furnace and in estimating the possibility of ash handling and slagging problems.

The *grindability index* indicates the ease with which a coal can be pulverized and is helpful in estimating ball mill capacity with various coals. These are two common methods for determining the index—hardgrove and ball mill.

The *free swelling index* denotes the extent of coal swelling on combustion on a fuel bed and indicates the coking characteristics of coal.

COMBUSTION CALCULATIONS

Calculations of the quantity of air required for combustion and the quantity of flue gas products generated during combustion are frequently needed for sizing system components and as input to efficiency calculations. Other calculations, such as values for excess air and theoretical CO_2, are useful in estimating combustion system performance.

Frequently, combustion calculations can be simplified by using molecular mass as the basis for calculations. Molecular mass can be expressed in any mass units. The pound molecular weight or pound mole is frequently used where the pound molecular weight of a compound equals the molecular weight of the compound expressed in pounds. (The molecular mass of a compound equals the sum of the atomic mass of each element in the compound.) A molecular mass of any substance contains the same number of molecules as a molecular mass of any other substance.

Corresponding to measurement standards common to the industries, calculations involving gaseous fuels are generally based on volume, while calculations involving liquid and solid fuels are generally based on mass.

Some calculations described here require data on concentrations of carbon dioxide, carbon monoxide, and oxygen in the flue gas. Gas analyses for CO_2, CO, and O_2 can be obtained by volumetric chemical analysis and other analytical techniques including electromechanical cells used in portable electronic flue gas analyzers.

Table 9 Typical Ultimate Analyses for Coals

Rank	As Received, Btu/lb	Constituents, Percent by Weight					
		Oxygen	Hydrogen	Carbon	Nitrogen	Sulfur	Ash
Anthracite	12,700	5.0	2.9	80.0	0.9	0.7	10.5
Semianthracite	13,600	5.0	3.9	80.4	1.1	1.1	8.5

Air Required for Combustion

Stoichiometric or theoretical air is the exact quantity of air required to provide oxygen for complete combustion.

The three most prevalent components in hydrocarbon fuels are completely combusted by the following reactions:

$$C + O_2 \rightarrow CO_2$$
$$H_2 + 0.5\ O_2 \rightarrow H_2O$$
$$S + O_2 \rightarrow SO_2$$

In the above reactions, C, H_2, S, and O_2 can be taken to represent 1 lb mole of carbon, hydrogen, sulfur, and oxygen, respectively. Using approximate atomic mass (C = 12, H = 1, S = 32, and O = 16), 12 lb of C are oxidized by 32 lb of O to form 44 lb of CO_2, 2 lb of H are oxidized by 16 lb of O to form 18 lb of H_2O, and 32 lb of S are oxidized by 32 lb of O to form 64 lb of SO_2. These relationships can be extended to include other hydrocarbon compounds.

The mass of dry air required to supply a given quantity of the oxygen is 4.32 times the mass of the oxygen. The mass of oxygen or air required to oxidize fuel constituents listed in Table 1 were calculated on this basis. Oxygen contained in the fuel, except that contained in ash, should be deducted from the amount of oxygen required, since this oxygen is already combined with fuel components. Also, water vapor is always present in atmospheric air, and when the mass of air to be supplied for combustion is calculated, allowance should be made for the water vapor.

As stated previously, combustion calculations are sometimes based on volume. Avogadro's law shows that, for any gas, one mole occupies the same volume at a given temperature and pressure. Therefore, in reactions involving gaseous compounds, the gases react in volume ratios identical to the pound mole ratios. That is, for the oxidation of hydrogen in the above reaction, one volume (or one lb mole) of hydrogen reacts with one-half volume (or one-half lb mole) of oxygen to form one volume (or one lb mole) of water vapor.

The volume of air required to supply a given volume of oxygen is 4.79 times the volume of oxygen. The volumes of oxygen or of dry air required to oxidize the fuel constituents listed in Table 1 were calculated on this basis. Volume ratios are not given for fuels that do not exist in vapor form at reasonable temperatures or pressures. Again, oxygen contained in the fuel should be deducted from the quantity of oxygen required, since this oxygen is already combined with fuel components. Allowance should be made for the water vapor that increases the volume of dry air by 1 to 3%.

From the relationships just described, the theoretical mass of dry air required for stoichiometric combustion of a unit mass of any hydrocarbon fuel is:

$$W_a = 0.0144\,(8\ C + 24\ H + 3\ S - 3\ O) \qquad (5)$$

where C, H, S, and O are the mass percentages of carbon, hydrogen, sulfur, and oxygen in the fuel, respectively.

Analyses of gaseous fuels are generally based on hydrocarbon components rather than elemental content.

If the fuel analysis is based on mass, the theoretical mass of dry air required for stoichiometric combustion of a unit mass of gaseous fuels is:

$$W_a = 2.47\ CO + 34.28\ H_2 + 17.24\ CH_4 + 16.09\ C_2H_6 + 15.68\ C_3H_8 + 15.47\ C_4H_{10} + 13.27\ C_2H_2 + 14.78\ C_2H_4 + 6.08\ H_2S - 4.32\ O_2 \qquad (6)$$

If the fuel analysis is reported on a volumetric or molecular basis, it is simplest to calculate air requirements based on volume and, if necessary, convert to mass. The theoretical volume of air required for stoichiometric combustion of a unit volume of gaseous fuels is:

$$V_a = 2.39\ CO + 2.39\ H_2 + 9.57\ CH_4 + 16.75\ C_2H_6 + 23.95\ C_3H_8 + 31.14\ C_4H_{10} + 11.96\ C_2H_2 + 14.38\ C_2H_4 + 7.18\ H_2S - 4.78\ O_2 + 30.47\ \text{illuminants} \qquad (7)$$

where CO, H_2, and so forth are the volumetric fractions of each constituent in the fuel gas.

Illuminants include a variety of compounds not separated by usual gas analysis. The principal illuminants, in addition to ethylene (C_2H_4) and acetylene (C_2H_2), included in Equation (7), and the dry air required for combustion, per unit volume of each gas, are: propylene (C_3H_6), 21.44; butylene (C_4H_8), 28.58; pentene (C_5H_{10}), 35.73; benzene (C_6H_6), 35.73; toluene (C_7H_8), 42.88; and xylene (C_8H_{10}), 50.02. Since toluene and xylene are normally scrubbed from the gas before distribution, they can be disregarded in computing air required for combustion of gaseous fuels. Since the percentage of illuminants present in gaseous fuels is small, the values can be lumped together, and an approximate value of 30 unit volume of dry air per unit volume of gas can be used. If ethylene and acetylene are included as illuminants, use the suggested value of 20 unit volume of dry air/unit volume of gaseous illuminants.

For many combustion calculations, only approximate values of air requirements are necessary. If approximate values for theoretical air are sufficient, or if complete information on the fuel is not available, the values in Tables 10 and 11 can be used. Another frequently used value for estimating air requirements is that 0.9 ft^3 of air is required for 100 Btu of fuel.

Excess air, in addition to the amount theoretically required for combustion, must be supplied to most practical combustion systems to ensure complete combustion.

$$\text{Excess air, \%} = 100\left(\frac{\text{Air supplied} - \text{Theoretical air}}{\text{Theoretical air}}\right) \qquad (8)$$

The excess air level at which a combustion process operates significantly affects its overall efficiency. Too much excess air dilutes flue gas excessively, lowering its heat transfer temperature and increasing sensible flue gas loss. Conversely, if the level of excess air is too low, incomplete combustion and loss of unburned combustible gases from the equipment can result. Highest combustion efficiency is usually obtained when just enough excess air is supplied and properly mixed with combustible gases to ensure complete combustion. The general practice is to supply from 5 to

Table 10 Approximate Air Requirements for Stoichiometric Combustion of Fuels

Type of Fuel	Air Required for Stoichiometric Combustion: lb/lb Fuel	Air Required for Stoichiometric Combustion: ft^3/Unit Fuel[a]	Approx. Precision, %	Exceptions
Solid	Btu/lb × 0.00073	Btu/lb × 0.0097	3	Fuels containing more than 30% water
Liquid	Btu/lb × 0.00071	Btu/lb × 0.0094	3	Results low for gasoline and kerosene
Gas	Btu/lb × 0.00067	Btu/ft^3 × 0.0089	5	300 Btu/ft^3 or less

Data based on Shnidman (1954).
[a] Units for solid and liquid fuels in Btu/lb; for gas in Btu/ft^3.

Table 11 Approximate Air Requirements for Stoichiometric Combustion of Various Fuels

Type of Fuel	Theoretical Air Required for Combustion
Solid fuels	lb/lb fuel
Anthracite	9.6
Semibituminous	11.2
Bituminous	10.3
Lignite	6.2
Coke	11.2
Liquid fuels	lb/gal fuel
No. 1 fuel oil	103
No. 2 fuel oil	106
No. 5 fuel oil	112
No. 6 fuel oil	114
Gaseous fuels	ft^3/ft^3 fuel
Natural gas	9.6
Butane	31.1
Propane	24.0

50% excess air, the exact amount depending on the type of fuel burned, combustion equipment, and other factors.

The amount of dry air supplied per unit mass of fuel burned can be obtained from Equation (9), which is reasonably precise for most solid and liquid fuels. Values for CO_2, CO, and N_2 are percentages by volume from the flue gas analysis, and C is the mass of carbon burned per unit mass of fuel, corrected for carbon in the ash.

$$\text{Dry air supplied, unit mass per unit mass of fuel} = \frac{C\,(3.04\,N_2)}{(CO_2 + CO)} \qquad (9)$$

This value, together with the value for theoretical air, can be used in Equation (8) to determine excess air.

Equation (10) can be used to calculate excess air on a percentage basis for fuel gas from unit volumes of stoichiometric combustion products and air, and volumetric analysis of the flue gas.

$$\text{Excess air, \%} = [(U - CO_2)/(CO_2)] \times 100\,(P/A) \qquad (10)$$

where

U = ultimate carbon dioxide of flue gases resulting from stoichiometric combustion, %
CO_2 = carbon dioxide content of flue gases, %
P = dry products from stoichiometric combustion, unit volume per unit volume of gas burned
A = air required for stoichiometric combustion, unit volume per unit volume of gas burned

As the ratio P/A is approximately 0.9 for most natural gases, a value of 90 can be substituted for 100 (P/A) in Equation (10) for rough calculation.

Because excess air calculations are almost invariably made from flue gas analysis results and theoretical air requirements are not always known, another convenient method of expressing the relation of Equation (8) is:

$$\text{Excess air, \%} = \frac{100[O_2 - (CO/2)]}{0.264\,N_2 - [O_2 - (CO/2)]} \qquad (11)$$

where O_2, CO, and N_2 are percentages (by volume) from the flue gas analysis.

Theoretical CO_2

The theoretical CO_2, ultimate CO_2, or maximum CO_2 concentration attainable in combustion products of a hydrocarbon fuel with air is the CO_2 concentration obtained when the fuel was completely burned with the theoretical quantity of air, or zero excess air. Theoretical CO_2 varies with the carbon-hydrogen ratio of the fuel. For combustion with excess air present, theoretical CO_2 values can be calculated from a flue-gas analysis:

$$\text{Theoretical } CO_2, \% = U = \frac{\%\ CO_2 \text{ in flue gas sample}}{1 - (\%\ O_2 \text{ in flue gas sample}/20.95)} \qquad (12)$$

Table 12 gives approximate theoretical CO_2 values for stoichiometric combustion of several common types of fuel, as well as CO_2 values attained with different amounts of excess air. In practice, desirable CO_2 values depend on the excess air, fuel, firing method, and other considerations.

Quantity of Flue Gas Produced

The mass of dry flue gas produced per pound of fuel burned is required in heat loss and efficiency calculations. This mass is equal to the sum of the mass of: (1) fuel (minus ash retained in the furnace), (2) air theoretically required for combustion, and (3) excess air. For solid fuels, this mass, determined from the flue gas analysis, is:

$$\frac{11\,CO_2 + 8\,O_2 + 7(CO + N_2)}{3(CO_2 + CO)}\ C \text{ lb/lb of fuel} \qquad (13)$$

where CO_2, O_2, CO, and N_2 are percentages by volume from the flue gas analysis, and C is the mass of carbon burned per pound of fuel, corrected for carbon in the ash.

Total dry gas volume of flue gases resulting from combustion of one unit volume of gaseous fuels for various percentages of CO_2 is:

$$\text{Dry flue gas, unit volume per unit volume of fuel gas} = \text{Unit volume of } CO_2 \text{ produced per unit volume of gas burned} \times 100/(\text{Percent } CO_2 \text{ by analysis}) \qquad (14)$$

Table 12 Approximate Maximum Theoretical (Stoichiometric) CO_2 Values, and CO_2 Values of Various Fuels with Different Percentages of Excess Air

Type of Fuel	Theoretical or Maximum CO_2, %	Percent CO_2 at Given Excess Air Values		
		20	40	60
Gaseous fuels				
Natural gas	12.1	9.9	8.4	7.3
Propane gas (Commercial)	13.9	11.4	9.6	8.4
Butane gas (Commercial)	14.1	11.6	9.8	8.5
Mixed gas (Natural and carbureted water gas)	11.2	12.5	10.5	9.1
Carbureted water gas	17.2	14.2	12.1	10.6
Coke oven gas	11.2	9.2	7.8	6.8
Liquid fuels				
No. 1 and 2 fuel oil	15.0	12.3	10.5	9.1
No. 6 fuel oil	16.5	13.6	11.6	10.1
Solid fuels				
Bituminous coal	18.2	15.1	12.9	11.3
Anthracite	20.2	16.8	14.4	12.6
Coke	21.0	17.5	15.0	13.0

Excess air quantity can be estimated by subtracting the quantity of dry flue gases resulting from stoichiometric combustion from the total volume of flue gas.

Water Vapor and Dew Point of Flue Gas

Water vapor in flue gas is the total of the water contained in the fuel; water contained in the stoichiometric, excess, and dilution air admitted; and water produced from the combustion of hydrogen or hydrocarbons in the fuel. The amount of water vapor in the stoichiometric combustion products may be calculated from the fuel burned by using the water data in Table 2.

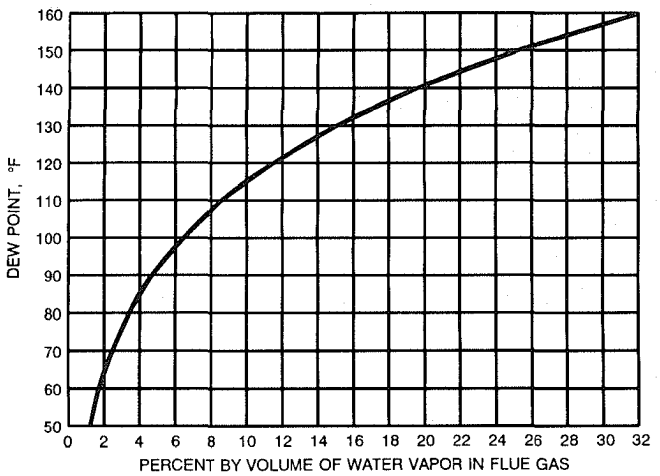

Fig. 2 Water Vapor and Dew Point of Flue Gas
Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

The dew point is the temperature at which condensation begins and can be determined from Figure 2. The volume percentage of water vapor P_{wv} in the flue gas can be determined as follows:

$$P_{wv} = \frac{V_w}{\frac{100\,V_c}{P_c} + V_w} \tag{15}$$

where

V_w = total water vapor volume (from fuel; stoichiometric, excess, and dilution air; and combustion)
V_c = unit volume of CO_2 produced per volume of fuel gas
P_c = percent CO_2 in flue gas

Using Figure 3, the dew points of solid, liquid, or gaseous fuels may be estimated. For example, to find the dew point of flue gas resulting from the combustion of a solid fuel with a weight ratio (hydrogen to carbon-plus-sulfur) of 0.088 and sufficient excess air to produce 11.4% oxygen in the flue gas, start with the weight ratio of 0.088. Proceed vertically to the intersection of the solid fuels curve and then to the theoretical dew point of 115 °F on the dew-point scale. See the dotted lines. Follow the curve fixed by this point (down and to the right) to 11.4% oxygen in the flue gas (on the abscissa). The actual dew point is 93 °F and is found on the dew-point scale.

The dew point of the flue gas from natural gas of 1020 Btu/ft^3 higher heating value (HHV) with 6.3% oxygen or 31.5% air can be estimated. Proceed vertically to the intersection of the gaseous fuels curve and then to the theoretical dew point of 139 °F on the dew-point scale. Follow the curve fixed by this point to 6.3% oxygen or 31.5% air in the flue gas. The actual dew point is 127 °F.

The presence of sulfur dioxide, and particularly sulfur trioxide, influences the vapor pressure of condensate in flue gas, and the dew point can be raised by as much as 25 to 75 °F, as shown in

Fig. 3 Theoretical Dew Points of Combustion Products of Industrial Fuels
Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

Figure 4. To illustrate the use of Figure 4, for a manufactured gas with a HHV of 550 Btu/ft^3 containing 15 grains of sulfur per 100 ft^3 being burned with 40% excess air, the proper curve in Figure 4 is determined as follows:

$$\frac{\text{Grains S per 100 ft}^3}{\text{Btu per cubic foot}} \times 100 \quad \text{or} \quad \frac{15}{500} \times 100 = 2.73 \qquad (16)$$

This curve lies between the 0- and 3-curves and is close to the 3-curve. The dew point for any percentage of excess air from zero to 100% can be determined on this curve. For this flue gas with 40% excess air, the dew point is about 160 °F, instead of 127 °F for zero sulfur at 40% excess air.

Sample Combustion Calculations

Applications of the preceding equations and tables are illustrated by Examples 1 and 2.

Example 1. Analysis of flue gases from the burning of a natural gas is 10.0% CO_2, 3.1% O_2, and 86.9% N_2 by volume. Analysis of the fuel is 90% CH_4, 5% N_2, and 5% C_2H_6 by volume. Find U (maximum theoretical percent CO_2) and the percent of excess air.

Solution: From Equation (12)

$$U = \frac{10.0}{1 - (3.1/20.95)} = 11.74\%\ CO_2$$

$$\text{From Equation (10), Excess air} = \frac{(11.74 - 10.0)\ 90}{10} = 15.66\%$$

Example 2. For the same analysis as in Example 1, find, per ft^3 of fuel gas, the ft^3 of dry air required for combustion, ft^3 of each constituent in the flue gases, and total volume of dry and wet flue gases.

Solution: From Equation (7) or Table 10, the volume of dry air required for combustion is

$$9.57\ CH_4 + 16.75\ C_2H_6 = (9.57 \times 0.90) + (16.75 \times 0.05)$$
$$= 9.45\ \text{ft}^3/\text{ft}^3\ \text{gas}$$

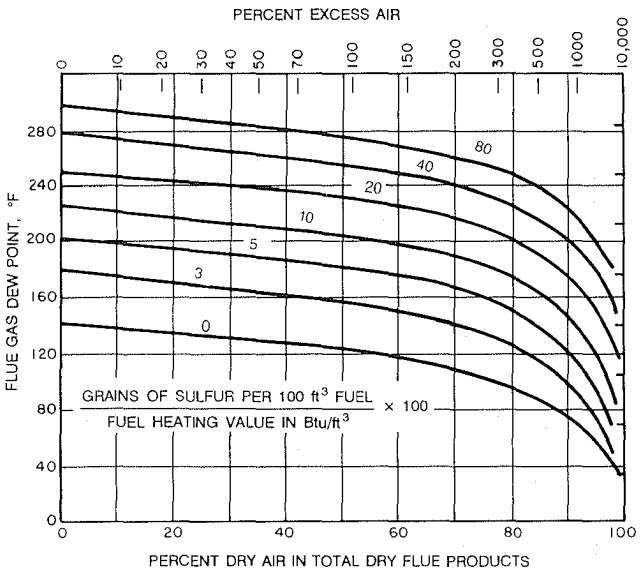

Fig. 4 Influence of Sulfur Oxides on Flue Gas Dew Point
(Stone 1969)

From Table 1, constituents per ft^3 of flue gas are:

Nitrogen, N_2		
From methane	$(0.9\ CH_4)(9.57 - 2.0)$	= 6.81
From ethane	$(0.05\ C_2H_6)(16.75 - 3.5)$	= 0.61
Nitrogen in fuel		= 0.05
Nitrogen in excess air	$0.791 \times 0.157 \times 9.45$	= 1.17
Total nitrogen		8.64 ft^3
Oxygen, O_2		
Oxygen in excess air	$0.209 \times 0.157 \times 9.45$	= 0.31 ft^3
Carbon dioxide, CO_2		
From methane	$(0.9\ CH_4)(1.0)$	= 0.90
From ethane	$(0.05\ C_2H_6)(2.0)$	= 0.10
Total carbon dioxide		1.00 ft^3
Water vapor, H_2O (does not appear in some flue gas analyses)		
From methane	$(0.9\ CH_4)(2.0)$	= 1.8
From ethane	$(0.05\ C_2H_6)(3.0)$	= 0.15
Total water vapor		1.95 ft^3

Total volume of dry gas per ft^3 of gas

$$8.64 + 0.31 + 1.00 = 9.95\ \text{ft}^3$$

Total volume of wet gases per ft^3 of gas (neglecting water vapor in combustion air)

$$9.95 + 1.95 = 11.90\ \text{ft}^3$$

The ft^3 of dry flue gas per ft^3 of fuel gas can also be computed from Equation (14)

$$(1.00)(100)/10.0 = 10.0\ \text{ft}^3$$

EFFICIENCY CALCULATIONS

Usually, in analyzing heating appliance efficiency, an energy balance is made that accounts (as much as possible) for disposition of all thermal energy released by combustion of the fuel quantity consumed. The various components of this balance are generally expressed in terms of Btu/lb of fuel burned or as a percentage of its higher heating value. Major components and their calculation methods are:

1. Useful heat, or heat transferred to the heated medium; for convection heating equipment, this value q_1 is computed as the product of the mass rate of flow and enthalpy change.
2. Heat loss as sensible heat in the dry flue gases

$$q_2 = w_g c_{pg}(t_g - t_a) \qquad (17)$$

3. Heat loss in water vapor in products formed by combustion

$$q_3 = (9H_2/100)[(h)_{tg} - (h_f)_{ta}] \qquad (18)$$

4. Heat loss in water vapor in the combustion air

$$q_4 = Mw_a[(h)_{tg} - (h_g)_{ta}] \qquad (19)$$

5. Heat loss from incomplete combustion

$$q_5 = 10{,}143\ C[CO/(CO_2 + CO)] \qquad (20)$$

6. Heat loss from unburned carbon in the ash or refuse

$$q_6 = 14{,}600[(C_u/100) - C] \qquad (21)$$

$(h_f)_{ta}$ = enthalpy of saturated water at air temperature, Btu/lb
t_g = temperature of flue gases at exit of heating device, °F
t_a = temperature of combustion air, °F
w_a = mass of combustion air per lb of fuel used [from Equations (5), (6), (8), (9), (10), and (11)], lb
w_g = mass of dry flue gas per lb of fuel [from Equation (13)], lb
c_{pg} = mean specific heat of flue gases at constant pressure [c_{pg} ranges from 0.242 to 0.254 Btu/lb·°F for flue gas temperatures from 300 to 1000°F], Btu/lb·°F
H_2 = hydrogen in fuel, percent by weight (from ultimate analysis of fuel)
M = specific humidity of combustion air, unit mass of water vapor per unit mass of dry air
CO, CO_2 = carbon monoxide and carbon dioxide in flue gases, percent by volume
C = mass of carbon burned, corrected for carbon in ash, lb/lb of fuel

$$C = (WC_u - W_aC_a)/(100W) \quad (22)$$

where

C_u = percentage of carbon in fuel by mass from ultimate analysis
W_a = mass of ash and refuse
C_a = percent of combustible in ash by mass (combustible in ash is usually considered to be carbon)
W = mass of fuel used

Item 1, useful heat, is generally measured for a particular piece of combustion equipment.

Flue gas loss is the sum of Items 2 through 6. However, for clean burning gas- and oil-fired equipment, Items 5 and 6 are usually not determined, and flue gas loss is taken to be the sum of Items 2, 3, and 4.

Flue gas losses (the sum of items 2, 3, and 4 of the heat balance) can be determined with sufficient precision for most purposes from curves in Figure 5, if O_2 content and flue gas temperature are known. Values of the losses were computed from typical ultimate analyses, and assuming 1% water vapor (by mass) in the combustion air. Curves for medium-volatile bituminous coal can be used for high-volatile bituminous coal with no appreciable error.

Generally, Item 5 is negligible for modern combustion equipment in good operating condition.

Item 6 is generally negligible for gas and oil firing, but should be determined for coal-firing applications.

Item 7 consists primarily of radiation and convection losses from combustion equipment surfaces and losses caused by incomplete combustion, not included in Items 5 and 6. Incomplete combustion is determined by subtracting the sum of Items 1 through 6 from the fuel heating value.

Radiation and convection losses are not usually determined by direct measurement. But if the heating appliance is located within the heated space, radiation and convection losses can be considered useful rather than lost heat and can be omitted from heat loss calculations or added to Item 1.

If CO is present in flue gases, small amounts of unburned hydrogen and hydrocarbons may also be present. The small losses caused by incomplete combustion of these gases would be included in Item 7, if the item was determined by subtracting Items 1 through 6 from the fuel heating value.

The overall thermal efficiency of combustion equipment is defined as:

$$\text{Thermal efficiency, \%} = 100 \frac{\text{Useful heat}}{\text{Heating value of fuel}} \quad (23)$$

Efficiency can be estimated for equipment, where Item 7 is small or radiation and convection are useful heat, by:

$$\text{Thermal efficiency, \%} = 100 \frac{\text{Heating value of fuel} - (q_2 + q_3 + q_4 + q_5 + q_6)}{\text{Heating value of fuel}} \quad (24)$$

The thermal efficiency of a gas appliance can be computed with sufficient precision, using heating values based on gas volume, by:

$$\eta = 100[(Q_g - Q_{fl})]/Q_g \quad (25)$$

where

η = thermal efficiency, %
Q_g = gross heating value of fuel gas per unit volume
Q_{fl} = flue gas losses per unit volume of fuel gas

To produce heat efficiently by burning any common fuel, flue gas losses must be minimized by: (1) providing adequate heat-absorbing surface in the appliance, (2) maintaining heat transfer surfaces clean on both fire and water or air sides, and (3) reducing excess air to the minimum level consistent with complete combustion and discharge of combustion products.

Seasonal Efficiency

The method just presented is useful for calculating the steady-state efficiency of a heating system or device. Unfortunately, the seasonal efficiency of a combustion heating system can be significantly different from the steady-state efficiency. The primary factor affecting the seasonal efficiency is flue loss during the burner-off period. The warm stack that exists at the end of the firing period can cause an airflow to be maintained in the stack while the burner is off. This airflow can remove heat from furnace and heat exchanger components, from the structure itself, and from pilot flames. Also, if combustion air is drawn from the heated space within the structure, there is a loss of heated air that must be replaced with cold infiltrated air. For discussion of seasonal efficiency, see Bibliography and Chapter 29 of the 1992 ASHRAE *Handbook—Systems and Equipment.*

PRACTICAL COMBUSTION CONSIDERATIONS

Air Pollution

Combustion processes constitute the largest single source of air pollution. Pollutants can be grouped in four categories:

1. Products of incomplete fuel combustion
   - Combustible aerosols (solid and liquid), including smoke, soot, and organics, and excluding ash
   - Carbon monoxide, CO
   - Gaseous hydrocarbons, HC

2. Oxides of nitrogen (generally grouped and referred to as NO_x)
   - Nitric oxide, NO
   - Nitrogen dioxide, NO_2
3. Emissions resulting from fuel contaminants
   - Sulfur oxides, primarily sulfur dioxide, SO_2, and small quantities of sulfur trioxide, SO_3
   - Ash
   - Trace metals
4. Emissions resulting from additives
   - Combustion-controlling additives
   - Other additives

Emissions of products of incomplete combustion and nitrogen oxides are directly related to the combustion process and can be controlled to some extent by process modification. Emissions of fuel contaminants are related to fuel selection and are slightly affected by the combustion process. Additives are used to achieve specific objectives; however, possible emission problems must be considered in an overall evaluation of the merits of using additives.

Emission levels of products of incomplete fuel combustion can be reduced by ensuring adequate excess air, improving mixing of air and fuel (increasing turbulence, improving distribution, and improving liquid fuel atomization), increasing residence time in the hot combustion zone (possibly by decreasing firing rate), increasing combustion zone temperatures (to speed reactions), and avoiding quenching the flame before reactions are completed.

Nitrogen oxides form during the combustion process, either (1) by thermal fixation (reaction of nitrogen and oxygen at high combustion temperatures), or (2) from fuel nitrogen (oxidation of organic nitrogen in fuel molecules). Unfortunately, high excess air and high flame temperature techniques for ensuring complete fuel combustion and, therefore, low emissions of incomplete combustion products, tend to promote increased NO_x formation.

Some methods of reducing NO_x emissions include (Murphy and Putnam 1985):

- Burner adjustment
- Flame inserts
- Staged combustion and delayed mixing
- Secondary air baffling
- Catalytic and radiant burners

Radiation screens (flame inserts) surrounding the flame will absorb radiation to reduce flame temperature and retard NO_x formation.

Two-stage or biased firing is the only technique that reduces NO_x produced both by thermal fixation and fuel nitrogen in industrial and utility applications. The lean or air-deficient primary combustion zone retards NO_x formation early in the combustion process (when NO_x forms most readily from fuel nitrogen), and peak temperatures are avoided, reducing thermal fixation. Two-stage firing is not practical in gas appliances because of increased complexity and dangerous interstage CO levels.

Proprietary appliance burners with no flame inserts have been developed and produced to comply with California's Air Quality Management Districts' NO_x emission restrictions. NO_x control techniques have also been widely applied to large boilers.

The practical minimums for NO_x emissions differ for different types of equipment as reflected in the regulatory maximum NO_x requirements. Table 13 lists the U.S. Environmental Protection Agency's maximums for large stationary sources (Engdahl and Barrett 1977, Barrett *et al.* 1977). The EPA's automobile emission standard is 1.0 g/mile of NO_2, equivalent to 750 ng/J of NO_x emission. California's maximum is 0.4 g/mile, equivalent to 300 ng/J. California's Air Quality Management Districts for the South Coast (Los Angeles) and the San Francisco Bay Area limit NO_x emission to 40 ng/J of useful heat for some natural gas-fired residential heating appliances.

Table 13 Maximum Emission Levels for Large Fossil Fuel-Fired Steam Generators

	Emission Level, lb/million Btu (ppm) Type of Fuel		
Species	Solid	Liquid	Gaseous
Particulates	0.21 (260)	0.21 (260)	0.21 (260)
SO_2	1.23 (1550)	0.79 (1000)	0.79 (1000)
NO_x as NO_2	0.72 (600)	0.30 (250)	0.21 (170)

Group 1 (larger than 2.56×10^8 Btu/h of fuel input, which may be equivalent to an electrical output of about 30 MW). Pollutants in lb/million Btu of fuel consumption. Numbers in parentheses refer to approximate stack conditions in parts per million, assuming stoichiometric combustion, mass/mass on a mass basis, volume/volume on a volume basis (EPA 1971a, 1971b).

For further discussion of air pollution aspects of fuel combustion, see EPA (1971a, 1971b).

Condensation and Corrosion

Fuel-burning systems that cycle on and off to meet demand cool down during the off-cycle. When the appliance starts again, condensate forms briefly on surfaces until they are heated above the dew-point temperature. Low-temperature corrosion occurs in system components (heat exchangers, flues, vents, chimneys) when their surfaces remain below the dew-point temperature of flue gas constituents (water vapor, sulfides, chlorides, fluorides, etc.) long enough to cause condensation. Corrosion increases as condensate dwell time increases.

Acids in the flue gas condensate are the principle substances responsible for low-temperature corrosion in fuel-fired systems. Sulfuric, hydrochloric, and other acids are formed when acidic compounds in fuel and air combustion products combine with condensed moisture in appliance heat exchangers, flues, or vents. Corrosion can be avoided by maintaining these surfaces above the flue gas dew point.

In high-efficiency, condensing-type appliances and economizers, the flue gas temperatures are intentionally reduced below the flue gas dew-point temperatures to achieve efficiencies approaching 100%. In these systems, the surfaces subjected to condensate must be made of corrosion-resistant materials. The most corrosive conditions exist at the leading edge of the condensing region, especially those areas that experience evaporation during each cycle (Strickland *et al.* 1987). Regions in which condensate partially or completely drains away before evaporation are less severely attacked than regions from which condensate does not drain before evaporation. Drainage of condensate retards the concentration of acids on system surfaces.

The metals most resistant to condensate corrosion are stainless-steel alloys, with high chrome and molybdenum content, and nickel-chrome alloys, with high molybdenum content (Stickford *et al.* 1988). Aluminum experiences general corrosion rather than pitting when exposed to flue gas condensate. If applied in sufficiently thick cross section to allow for metal loss, aluminum can be used in condensing regions. Most ceramic and high-temperature polymer materials resist the corrosive effects of flue gas condensate. These materials may have application in the condensing regions, if they can meet the structural and temperature requirements of a particular application.

In coal-fired power plants, the rate of corrosion for carbon steel condensing surfaces by the mixed acids (primarily sulfuric and hydrochloric) is reported to be maximum at about 122 ± 18°F (Davis 1987). Mitigation techniques have included (1) acid neutralization with a base, for example, NH_3 or $Ca(OH)_2$; (2) use of protective linings of glass-filled polyester or coal-tar epoxy; and (3) replacement of steel with molybdenum bearing stainless steels, nickel alloys, polymers, or other corrosion-resistant materials.

Other elements in residual fuel oils and coals that contribute to high-temperature corrosion include sodium, potassium, and vanadium. Each fuel-burning system component should be evaluated during installation, or when modified, to determine the potential for corrosion and the means to retard corrosion (Paul *et al.* 1988).

Soot

Soot deposits on flue surfaces of a boiler or heater act as an insulating layer over the surface, reducing heat transfer to the water or air. Soot can also clog flues, reduce draft and available air, and prevent proper combustion. Proper burner adjustment can minimize soot accumulation.

CHAPTER 16

REFRIGERANTS

Refrigerant Properties 16.1
Refrigerant Performance 16.2
Safety 16.5
Leak Detection 16.6
Effect on Construction Materials 16.9

REFRIGERANTS are the vital working fluids in refrigeration, air-conditioning, and heat pumping systems. They absorb heat from one area, such as an air-conditioned space, and reject it into another, such as outdoors, usually through evaporation and condensation processes, respectively. These phase changes occur both in absorption and mechanical vapor compression systems, but they do not occur in systems operating on a gas cycle using a fluid such as air. The design of the refrigeration equipment depends strongly on the properties of the selected refrigerant. Table 1 lists ASHRAE standard refrigerant designations.

A refrigerant must satisfy many requirements, some of which do not directly relate to its ability to transfer heat. Chemical stability under conditions of use is the most important characteristic. Safety codes may require a nonflammable refrigerant of low toxicity for some applications. Cost, availability, and compatibility with compressor lubricants and materials with which the equipment is constructed are other concerns.

The environmental consequences of a refrigerant that leaks from a system must also be considered. Because of their great stability, fully halogenated compounds, called CFCs, persist in the atmosphere for many years and eventually diffuse into the stratosphere. The molecules of CFCs, such as R11 and R12, contain only carbon and the halogens chlorine, fluorine, and/or bromine. Once in the upper atmosphere, the refrigerant molecule breaks down and releases chlorine, which destroys ozone. In the lower atmosphere, these molecules absorb infrared radiation, which may contribute to the warming of the earth. Substitution of a hydrogen atom for one or more of the halogens in a CFC molecule greatly reduces its atmospheric lifetime and lessens its environmental impact.

Refrigerant selection also involves compromises between conflicting desirable thermodynamic properties. A desirable refrigeration system has an evaporator pressure as high as possible and, simultaneously, a condenser pressure as low as possible. High evaporator pressures imply high vapor densities, and thus a greater system capacity for a given compressor. However, the efficiency at the higher pressures is lower, especially as the condenser pressure approaches the critical pressure.

Latent heat of vaporization is another important property. On a molar basis, fluids with similar boiling points have almost the same latent heat. Since the compressor operates on volumes of gas, refrigerants with similar boiling points produce similar capacities in a given compressor. On a mass basis, latent heat varies widely among fluids. The maximum efficiency of a theoretical vapor compression cycle is achieved by fluids with low vapor heat capacity. This property is associated with fluids having a simple molecular structure and low molecular weight.

Transport properties of thermal conductivity and viscosity affect the performance of heat exchangers and piping. High thermal conductivity and viscosity affect the performance of heat exchangers and piping. High thermal conductivity and low viscosity are desirable.

The preparation of this chapter is assigned to TC 3.1, Refrigerants and Brines.

No single fluid satisfies all the attributes desired of a refrigerant; as a result, a variety of refrigerants is used. This chapter describes the basic characteristics of various refrigerants, and Chapter 17 lists thermophysical properties.

REFRIGERANT PROPERTIES

Physical Properties

Table 2 lists some physical properties of commonly used refrigerants, a few very low-boiling cryogenic fluids, some newer refrigerants, and some older refrigerants of historical interest. These refrigerants are arranged in increasing order of atmospheric boiling point, from helium at −452°F to water at 212°F.

Table 2 also includes the boiling point, freezing point, critical properties, surface tension, and refractive index. Of these properties, the boiling point is most important because it is a direct indicator of the temperature level at which a refrigerant can be used. The freezing point must be lower than any contemplated usage. The critical properties describe a material at the point where the distinction between liquid and gas is lost. At higher temperatures, no separate liquid phase is possible. In refrigeration cycles involving condensation, a refrigerant must be chosen that allows this change of state to occur at a temperature somewhat below the critical.

Lithium bromide-water and ammonia-water solutions. Figure 1 shows specific gravity, Figure 2 specific heat, and Figure 3 viscosity of lithium bromide-water solutions. Chapter 17 has an enthalpy concentration chart and a vapor pressure diagram for lithium bromide-water solutions; it also lists equilibrium properties of water-ammonia solutions.

Electrical Properties

Tables 3 and 4 list the electrical characteristics of refrigerants that are especially important in hermetic systems.

Sound Velocity

Table 5 gives examples of the velocity of sound in the vapor phase of several fluorinated refrigerants. The velocity increases when the temperature is increased and decreases when the pressure is increased. The velocity of sound can be calculated from the equation

$$V_a = \sqrt{g(dp/d\rho)_s} = \sqrt{g\gamma(dp/d\rho)_T} \qquad (1)$$

where

V_a = sound velocity, ft/s
g = 32.1740 ft/s²
p = pressure, lb/ft², absolute
ρ = density, lb/ft²
$\gamma = c_p/c_v$ = ratio of specific heats
S = entropy, Btu/lb·°R
T = temperature, °R

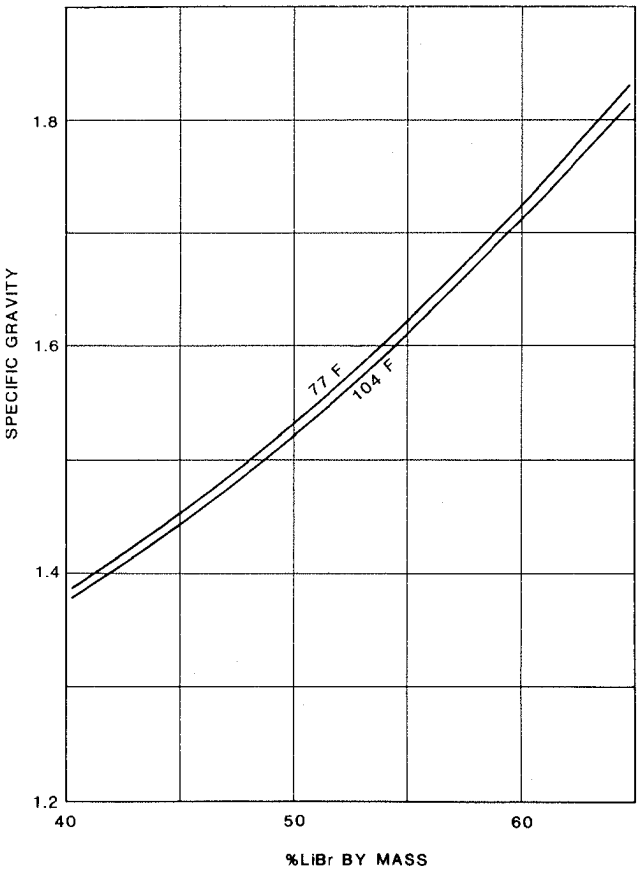

Fig. 1 Specific Gravity of Aqueous Solutions of Lithium Bromide

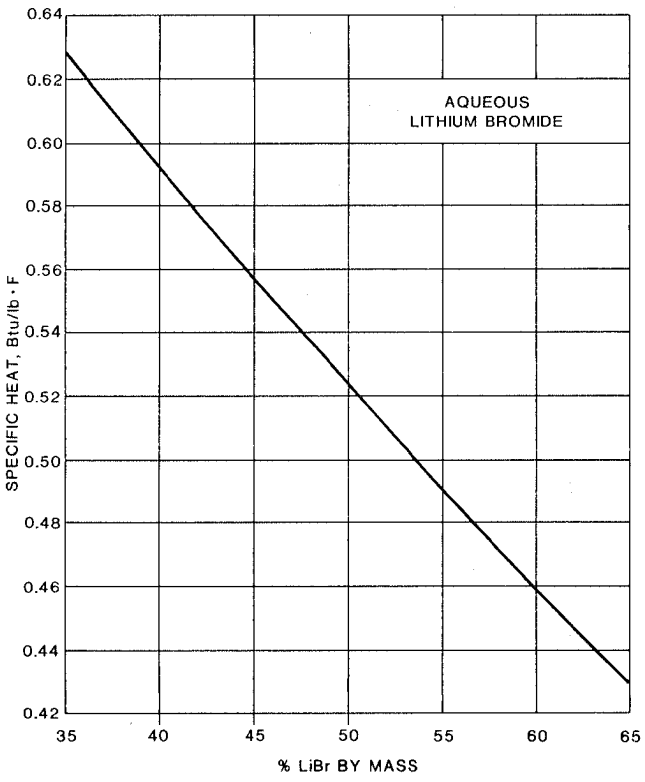

Fig. 2 Specific Heat of Aqueous Solutions of Lithium Bromide

The sound velocity can be estimated from the tables of thermodynamic properties. The change in pressure with a change in density ($dp/d\rho$) can be estimated either at constant entropy or at constant temperature. It is simpler to estimate at constant temperature but, in this case, the heat capacity ratio must also be known as previously shown. The practical velocity of a gas in piping or through openings is limited by the sound velocity in the gas.

Latent Heat

An empirical rule of chemistry (Trouton's rule) states that the latent heat of vaporization at the boiling point on a molar basis, divided by the temperature in absolute units, is a constant for most materials. This rule is applied to refrigerants in Table 6. It applies fairly well to these refrigerants, although the result is not entirely constant. The rule helps in comparing different refrigerants and in understanding the operation of refrigeration systems.

REFRIGERANT PERFORMANCE

Chapter 1 describes several methods of calculating refrigerant performance, and Chapter 17 includes tables of thermodynamic properties of the various refrigerants.

Table 7 shows the theoretical calculated performance of a number of refrigerants for the U.S. standard cycle of 5 °F evaporation

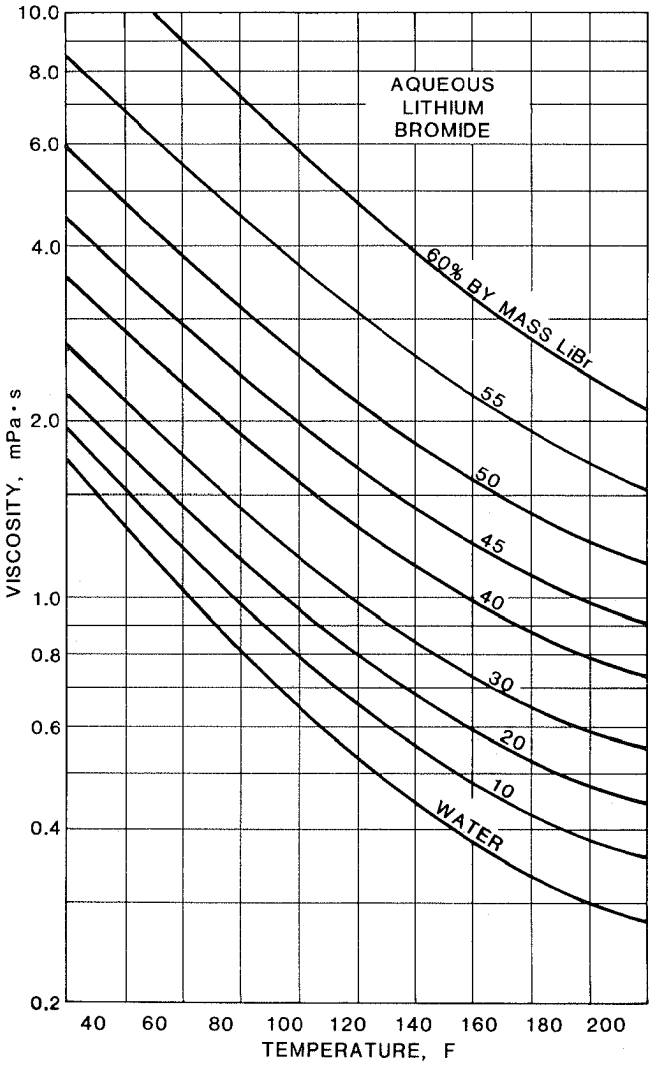

Fig. 3 Viscosities of Aqueous Solutions of Lithium Bromide

Table 1 ASHRAE Standard Designation of Refrigerants (ANSI/ASHRAE *Standard* 34-1992)

Refrigerant Number	Chemical Name or Composition	Chemical Formula
Methane Series		
10	tetrachloramethane (carbon tetrachloride)	CCl_4
11	trichlorofluoromethane	CCl_3F
12	dichlorodifluoromethane	CCl_2F_2
12B1	bromochlorodifluoromethane	$CBrClF_2$
12B2	dibromodifluoromethane	CBr_2F_2
13	chlorotrifluoromethane	$CClF_3$
13B1	bromotrifluoromethane	$CBrF_3$

and 86 °F condensation. Calculated data for other conditions are given in Table 8. The tables can be used to compare the properties of different refrigerants, but actual operating conditions are somewhat different from the calculated data. In most cases, the suction vapor is assumed to be saturated, and the compression is assumed adiabatic or at constant entropy. For R-113 and R-114, these assumptions would cause some liquid in the discharge vapor. In these cases, it is assumed that the discharge vapor is saturated and that the suction vapor is slightly superheated. In Section F of Table 8, the temperature of the suction gas is assumed to be 65 °F. Comparison with Section E illustrates the effect of suction gas superheating on the refrigerant properties.

The comparisons shown in Tables 9 and 10 are based on constant compressor displacement. They illustrate the effect of different evaporating and condensing temperatures on theoretical capacity and horsepower of compression.

SAFETY

Table 11 summarizes the toxicity and flammability characteristics of many refrigerants. In ANSI/ASHRAE *Standard* 15-1992, refrigerants are classified according to the hazard involved in their use. Group A1 refrigerants are the least hazardous, Group B3 the most hazardous.

LEAK DETECTION

Leak detection in refrigeration equipment is a major problem for manufacturers and service engineers. The following sections describe several leak detection methods.

Electronic Detector

The electronic detector is widely used in the manufacture and assembly of refrigeration equipment. Instrument operation depends on the variation in current flow caused by ionization of decomposed refrigerant between two oppositely charged platinum electrodes. This instrument can detect any of the halogenated refrigerants except R-14. *It is not recommended for use in atmospheres containing explosive or flammable vapors.* Other vapors, such as alcohol and carbon monoxide, may interfere with the test.

The electronic detector is the most sensitive of the various leak detection methods, reportedly capable of sensing a leak of 1/100 oz per year of R-12.

A portable model is available for field testing. Other models are available with automatic balancing systems that correct for refrigerant vapors that might be present in the atmosphere around the test area.

Halide Torch

The halide torch is a fast and reliable method of detecting leaks of halogenated refrigerants. Air is drawn over a copper element heated by a methyl alcohol or hydrocarbon flame. If halogenated vapors are present, they decompose, and the color of the flame changes to bluish-green. Although not as sensitive as the electronic detector, this method is suitable for most purposes.

Bubble Method

The object to be tested is pressurized with air or nitrogen. A pressure corresponding to operating conditions is generally used. The object is immersed in water, and any leaks are detected by observing the formation of bubbles in the liquid. Adding a detergent to the water decreases the surface tension, prevents escaping gas from clinging to the side of the object, and promotes the formation of a regular stream of small bubbles. Kerosene or other organic liquids are sometimes used for the same reason. A solution of soap or detergent can be brushed or poured onto joints or other spots where leakage is suspected. Leaking gas forms soap bubbles that can be readily detected.

Detection of Ammonia and Sulfur Dioxide Leaks

Ammonia can be detected by burning a sulfur candle in the vicinity of the suspected leak or by bringing a solution of hydrochloric acid near the object. If ammonia vapor is present, a white cloud or smoke of ammonium sulfite or ammonium chloride forms. Ammonia can also be detected with indicating paper that changes color in the presence of a base.

Sulfur dioxide can be detected by the appearance of white smoke when aqueous ammonia is brought near the leak.

Table 7 Comparative Refrigerant Performance per Ton of Refrigeration

Refrigerant No.	Refrigerant Name	Evaporator Pressure, psia	Condensing Pressure, psia	Compression Ratio	Net Refrigerating Effect, Btu/lb	Refrigerant Circulated, lb/min	Liquid Circulated, in^3/min	Specific Volume of Suction Gas, ft^3/lb	Compressor Displacement, cfm	Horsepower hp	Coefficient of Performance	Comp. 40	0.20	0.43	0.68	0.98

Leaks can also be determined by pressurizing or evacuating and observing the change in pressure or vacuum over a period of time. This is effective in checking the tightness of the system but does not locate the point of leakage.

EFFECT ON CONSTRUCTION MATERIALS

Metals

Halogenated refrigerants can be used satisfactorily under normal conditions with most common metals, such as steel, cast iron, brass, copper, tin, lead, and aluminum. Under more severe conditions, various metals affect such properties as hydrolysis and thermal decomposition in varying degrees. The tendency of metals to promote thermal decomposition of halogenated compounds is in the following order:

(Least decomposition) Inconel < 18-8 stainless steel < nickel < copper < 1340 steel < aluminum < bronze < brass < zinc < silver (most decomposition)

This order is only approximate, and exceptions may be found for individual compounds or for special use conditions. The effect of metals on hydrolysis is probably similar.

Magnesium, zinc, and aluminum alloys containing more than 2% magnesium are not recommended for use with halogenated compounds where even trace amounts of water may be present.

Warning: Never use methyl chloride with aluminum in any form. A highly flammable gas is formed and the explosion hazard is great.

Ammonia should never be used with copper, brass, or other alloys containing copper. When water is present in sulfur dioxide systems, sulfurous acid is formed and can attack iron or steel rapidly and other metals at a slower rate.

Table 11 Comparison of Safety Group Classifications to Those under ASHRAE *Standard* 34-1989

Elastomers

The linear swelling of some elastomers in the liquid phase of various refrigerants is shown in Table 12. Swelling data can be used to a limited extent in comparing the effect of refrigerants on elastomers. However, other factors, such as the amount of extraction, tensile strength, and degree of hardness of the exposed elastomer must be considered. When other fluids are present in addition to the refrigerant, the combined effect on elastomers should be determined. In some instances, somewhat higher swelling of elastomers is found in mixtures of R-22 and lubricating oil than in either fluid alone. Table 13 shows the diffusion of water through elastomers.

Plastics

The effect of a refrigerant on a plastic material should be thoroughly examined under the conditions of intended use. Plastics are often mixtures of two or more basic types, and it is difficult to predict the effect of the refrigerant. The linear swelling of some plastic materials in refrigerants is shown in Table 14. Swelling data can be used as a guide but, as with elastomers, the effect on the properties of the plastic should also be examined. Comparable

CHAPTER 17

REFRIGERANT TABLES AND CHARTS

THIS chapter presents tabular data for the thermodynamic and transport properties of refrigerants arranged for the occasional user. Each refrigerant has a thermodynamic property chart on pressure-enthalpy coordinates with an abbreviated set of tabular data for the saturated liquid and vapor on the facing page. In addition, tabular data in the superheated vapor region are given for R-134a to assist in working on compression cycle examples. New for this Handbook are data for several "new" or "alternative" refrigerants, namely, R-32, R-123, R-124, R-125, R-134a, and R-141b. All of the CFC refrigerants have been retained to assist in making comparisons. Revised formulations, especially for the transport properties, have been used for a number of refrigerants; the formulations used are detailed in the References section.

The reference states used for most of the refrigerants correspond to the international convention of 200 kJ/kg for enthalpy and 1.00 kJ/(kg·K) for entropy, both for the saturated liquid at 0°C. For this I-P edition, the traditional American convention of 0 Btu/lb and 0 Btu/lb·°F for enthalpy and entropy, respectively, for the saturated liquid at −40°F is used. The exceptions are water and fluids which have very low critical temperatures, such as R-14 and the cryogens.

These data are intended to help engineers make preliminary comparisons among unfamiliar fluids. For greater detail and a wider range of data, consult the sources listed in the References section at the end of the chapter and/or ASHRAE *Thermodynamic Properties of Refrigerants* (1985) and ASHRAE *Thermophysical Properties of Refrigerants* (1993).

REFERENCES

The sources for the tabular data in this chapter are listed by fluid and property. The reference listed under "equation of state" is the source for vapor pressure, liquid density, vapor volume, enthalpy, entropy, specific heat, and the velocity of sound, unless indicated otherwise by additional entries for one or more of these properties. Transport properties for many of the refrigerants have been updated as part of ASHRAE research project 558RP (Liley 1993); the values in the tables in this Handbook were calculated from the equations given by Liley (1993) and may differ slightly from the tabular values given by Liley. Data for the hydrocarbon refrigerants, cryogens, absorption solutions, and several of the CFC refrigerants have been copied directly from the 1989 Handbook; these are indicated by a (*) preceding the citation.

R-11

Equation of state:
Jacobsen, R.T., S.G. Penoncello, and E.W. Lemmon. 1992. A fundamental equation for trichlorofluoromethane (R-11). *Fluid Phase Equilibria* 80(11):45-56.

CHAPTER 18

SECONDARY COOLANTS (BRINES)

Brines 18.1
Inhibited Glycols 18.4
Halocarbons 18.12
Nonhalocarbon, Nonaqueous Fluids 18.12

IN many refrigeration applications, heat is transferred to a secondary coolant, which can be any liquid cooled by the refrigerant and used to transfer heat without changing state. These liquids are known as *heat transfer fluids*, *brines*, or *secondary refrigerants*.

Other ASHRAE Handbooks describe various applications for secondary coolants. In the 1990 ASHRAE *Handbook—Refrigeration*, refrigeration systems are discussed in Chapter 5; their uses in food processing are found in Chapters 9, 12, and 14; ice rinks are discussed in Chapter 34; and environmental test facilities are covered in Chapter 37. In the 1991 ASHRAE *Handbook—Applications*, solar energy utilization is discussed in Chapter 39, thermal storage in Chapter 39, and snow melting in Chapter 45.

This chapter describes the physical properties of several secondary coolants and provides information on their use. The chapter also includes information on corrosion protection. Additional information on corrosion inhibition can be found in Chapter 43 of the 1991 ASHRAE *Handbook—Applications* and Chapter 5 of the 1990 ASHRAE *Handbook—Refrigeration*.

BRINES

Properties

Water solutions of calcium and sodium chloride are the most common refrigeration brines. Tables 1 and 2 list the properties of pure calcium chloride brine and sodium chloride brine. For commercial grades, use the formulae indicated in the footnotes to these tables. Figures 1 and 5 give the specific heats for liquid brines and are used for computation of heat loads with ordinary brine (Carrier 1959). Figures 2 and 6 show the ratio of the mass of the solution to that of water, which is commonly used as the measure of salt concentration. Viscosities are given in Figures 3 and 7. Figures 4 and 8 show thermal conductivity of calcium and sodium brines at varying temperatures and concentrations.

Brine applications in refrigeration are mainly in the industrial machinery field and in skating rinks. Corrosion is the principal problem for calcium chloride brines, especially in ice-making tanks where galvanized iron cans are immersed.

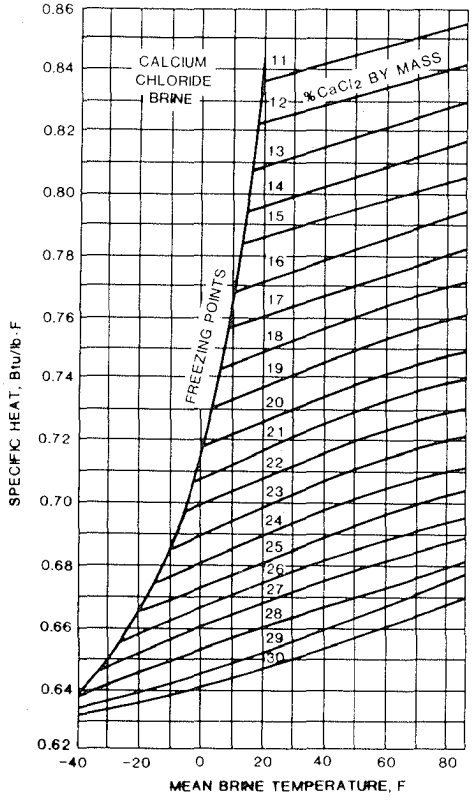

Fig. 1 Specific Heat of Calcium Chloride Brine

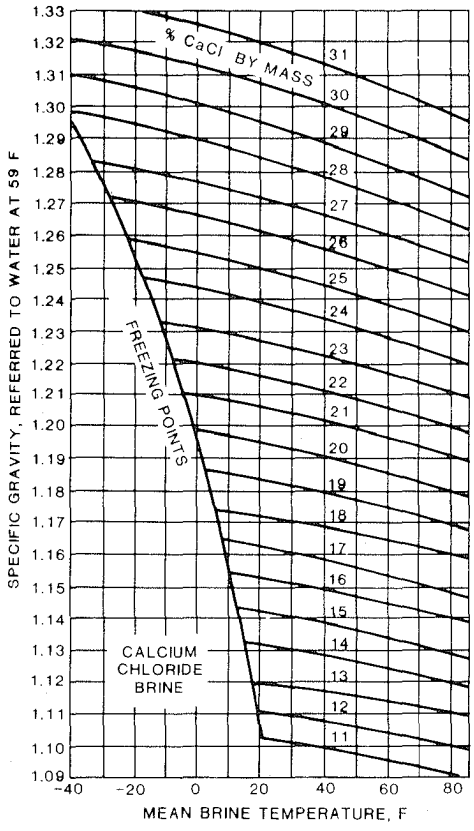

Fig. 2 Density of Calcium Chloride Brine

The preparation of this chapter is assigned to TC 3.1, Refrigerants and Brines.

[a]Mass of Type 1 (77% min) $CaCl_2$ = (mass of pure $CaCl_2$)/(0.77). Mass of Type 2 (94% min) $CaCl_2$ = (mass of pure $CaCl_2$)/(0.94).
[b]Mass of water per unit volume = Brine mass minus $CaCl_2$ mass.

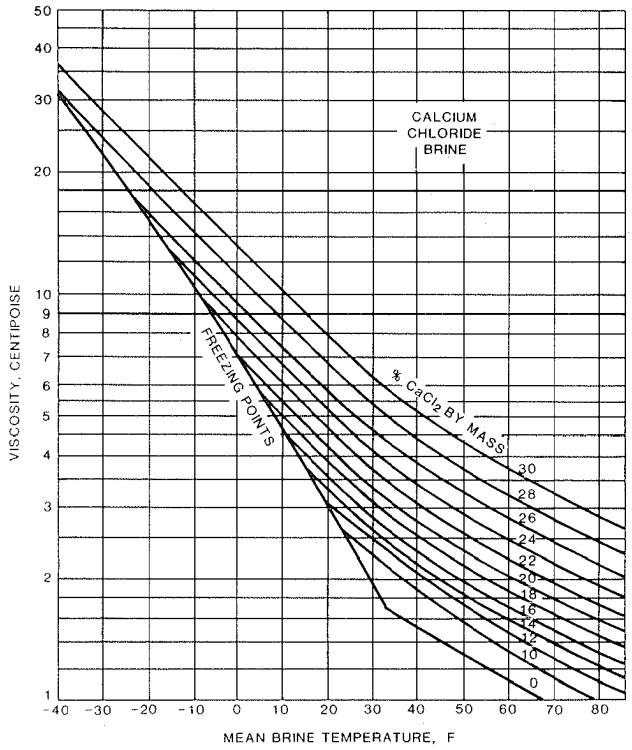

Fig. 3 Viscosity of Calcium Chloride Brine

Ordinary salt (sodium chloride) is used where contact with calcium chloride is intolerable, *e.g.*, the brine fog method of freezing fish and other foods. It is used as a spray in air cooling of unit coolers to prevent frost formation on coils. In most refrigerating work, the lower freezing point of calcium chloride solution makes it more convenient to use.

Commercial calcium chloride, available as Type 1 (77% min) and Type 2 (94% min), is marketed in flake, solid, and solution forms; flake form is used most extensively. Commercial sodium chloride is available both in crude (rock salt) and refined grades. Because magnesium salts tend to form sludge, their presence in sodium or calcium chloride is undesirable.

Corrosion

Brine systems must be treated to control corrosion and deposits. The standard chromate treatment program is the most effective. Calcium chloride brines require a minimum of 1800 ppm of sodium chromate with pH 6.5 to 8.5. Sodium chloride brines require a minimum of 3600 ppm of sodium chromate and a pH of 6.5 to 8.5. Sodium nitrite at 3000 ppm in calcium brines or 4000 ppm in sodium brines will control pH between 7.0 and 8.5, and should provide adequate protection. Organic inhibitors are available that may provide adequate protection where neither chromates nor nitrites can be used.

Before using any chromate-based inhibitor package, review federal, state, and local regulations concerning the use and disposal of chromate-containing fluids. If the regulations prove too restrictive, an alternative inhibition system should be considered.

INHIBITED GLYCOLS

Ethylene glycol and propylene glycol, inhibited for corrosion control, are used as aqueous freezing point depressants and heat transfer media in heating and cooling systems. Their chief attributes are their ability to lower the freezing point of water, low volatility, and relatively low corrosivity when properly inhibited.

Inhibited ethylene glycol solutions have better physical properties than propylene glycol solutions, especially at lower temperatures. However, the less toxic propylene glycol is preferred for applications involving possible human contact or where mandated by regulations.

Physical Properties

Ethylene and propylene glycol are colorless, practically odorless liquids that are miscible with water and many organic compounds. Table 3 shows properties of the pure materials.

Table 3 Summary of Physical Properties

Property	Ethylene Glycol	Propylene Glycol
Molecular weight	62.07	76.10
Ratio of mass to water at 68/68°F	1.1155	1.0381
Density at 68°F		
lb/ft³	69.50	64.68
lb/gal	9.29	8.65
Boiling point, °F		
at 760 mm Hg	388	369
at 50 mm Hg	253	241
at 10 mm Hg	192	185
Vapor pressure, at 68°F, mm Hg	0.05	0.07
Freezing point, °F	9.1	Sets to glass below −76°F
Viscosity, centipoise		
at 32°F	57.4	243
at 68°F	20.9	60.5
at 104°F	9.5	18.0
Refractive index, n_D, at 68°F	1.4319	1.4329
Specific heat at 68°F, Btu/lb·°F	0.561	0.593
Heat of fusion at 9.1°F, Btu/lb	80.5	—
Heat of vaporization at 1 atm, Btu/lb	364	296
Heat of combustion at 68°F, Btu/lb	8280	10,312

The freezing and boiling points of aqueous solutions of ethylene glycol and propylene glycol are given in Tables 4 and 5. Note that increasing the concentration of ethylene glycol above 60% by mass causes the freezing point of the solution to increase. Propylene glycol solutions above 60% by mass do not have freezing points. Instead of freezing, propylene glycol solutions become a glass (glass being an amorphous, undercooled liquid of extremely high viscosities that has all the appearances of a solid). On the dilute side of the eutectic, ice forms on freezing; on the concentrated side, solid glycol separates from solution on freezing. Freezing velocity of such solutions is often quite slow; but, in time, they set to a hard, solid mass.

Physical properties, *i.e.*, specific heat, specific gravity, viscosity, and thermal conductivity, for aqueous solutions of ethylene glycol can be found in Tables 6 through 9 and Figures 9 through 12; data for aqueous solutions of propylene glycol can be found in Tables 10 through 13 and Figures 13 through 16. Densities are for aqueous solutions of industrially inhibited glycols. These densities are somewhat higher than those for pure glycol and water alone. Typical corrosion inhibitor packages do not significantly affect the other physical properties. The physical properties for the two fluids are similar, with the exception of viscosity. Aqueous solutions of propylene glycol are more viscous than similar concentration solutions of ethylene glycol-water. This higher viscosity

accounts for the majority of the performance difference between the two fluids.

The choice of glycol concentration depends on the type of protection required by the application. If the fluid is being used to prevent equipment damage during idle periods in cold weather, such as winterizing coils in an HVAC system, 30% ethylene glycol or 35% propylene glycol is sufficient. These concentrations will allow the fluid to freeze. As the fluid freezes, it forms a slush that expands and flows to any available space. Therefore, expansion volume must be included with this type of protection. If the application requires that the fluid remain entirely liquid, a concentration with a freezing point 5 °F below the lowest expected temperature should be chosen. Avoid excessive glycol concentration because it only increases initial cost and adversely affects the physical properties of the fluid.

Additional physical property data is available from suppliers of industrially inhibited ethylene and propylene glycol.

Corrosion Inhibition

Commercial ethylene or propylene glycol, when pure, is generally less corrosive than water to common metals used in construction. However, aqueous solutions of these glycols assume the corrosivity of the water from which they are prepared and can become increasingly corrosive with use if they are not properly inhibited. Without inhibitors, glycols oxidize into acidic end products. The amount of oxidation is influenced by temperature, degree of aeration, and, to some extent, the particular combination of metal components to which the glycol solution is exposed.

Corrosion inhibition can be described by classifying additives as either (1) corrosion inhibitors, or (2) environmental stabilizers and adjusters. Corrosion inhibitors form a surface barrier that protects the metal from attack. These barriers are usually formed by adsorption of the inhibitor by the metal, by reaction of the inhibitor with the metal, or by the incipient reaction product. In most cases, metal surfaces are covered by films of their oxides that inhibitors reinforce.

Environmental stabilizers or adjusters, while not corrosion inhibitors in the strict sense, decrease corrosion by stabilizing or favorably altering the overall environment. An alkaline buffer such as borax is an example of an environmental stabilizer, since its prime purpose is to maintain an alkaline condition (pH above 7). Some chelating agents function as stabilizers by removing from the solution certain deleterious ions that accelerate the corrosion process or mechanism; however, exercise caution in their use as improper combinations of pH and concentration may lead to excessive corrosion.

Certain oxidants, such as sodium chromate, should not be used with glycol solutions, because the glycol can oxidize prematurely. Generally, combinations of the two types of additives, inhibitors, and stabilizers offer the best corrosion resistance in a given system. Commercial inhibited glycols are available from several suppliers.

Service Considerations

Design considerations. Inhibited glycols can be used at temperatures as high as 350 °F. However, maximum-use temperatures vary from fluid to fluid. Therefore, the manufacturer's suggested temperature-use ranges should be followed. In systems with a high degree of aeration, the bulk fluid temperature should not exceed 180 °F, but up to 350 °F is permissible in a pressurized system if air intake is eliminated. Maximum film temperatures should not exceed 50 °F above the bulk temperature. Nitrogen blanketing will minimize oxidation when the system operates at elevated temperatures for extended periods.

Minimum operating temperatures are typically −10 °F for ethylene glycol solutions and 0 °F for propylene glycol solutions. Operation below these temperatures is generally impractical, as the viscosity of the fluids builds dramatically, thus increasing pumping horsepower requirements and reducing heat transfer film coefficients.

Standard materials can be used with most inhibited glycol solutions except galvanized steel, because the galvanizing material, zinc, will react with a portion of the inhibitor package found in most formulated glycols.

Because the removal of active sludge and other contaminants is critical, install suitable filters. If inhibitors are rapidly and completely adsorbed by such contamination, the fluid is ineffective for corrosion inhibition. Consider such adsorption when selecting filters.

Storage and handling. Inhibited glycol concentrates are stable, relatively noncorrosive materials with high flash points. These fluids can be stored in mild steel, stainless steel, or aluminum vessels. However, aluminum should be used only when the fluid temperature is below 150 °F. Corrosion in the vapor space of vessels may be a problem, because the fluid's inhibitor package cannot reach these surfaces to protect them. To prevent this problem, a coating may be used. Suitable coatings include novolac-based vinyl ester resins, high-bake phenolic resins, polypropylene, and polyvinylidene fluoride. To ensure the coating is suitable for a particular application and temperature, the manufacturer should

be consulted. Since chemical properties of an inhibited glycol concentrate differ from those of its dilution, the effect of the concentrate on different containers should be known when selecting storage.

Choose transfer pumps only after considering temperature-viscosity data. Centrifugal pumps with electric motor drives are often used. Materials compatible with ethylene or propylene glycol should be used for pump packing material. Mechanical seals are also satisfactory. Welded mild steel transfer piping with a minimum diameter is normally used in conjunction with the piping, although flanged and gasketed joints are also satisfactory.

Preparation before application. Before an inhibited glycol is charged into a system, remove residual contaminants such as sludge, rust, brine deposits, and oil so the contained inhibitor functions properly. Avoid strong acid cleaners; if they are required, consider inhibited acids. Completely remove the cleaning agent before charging with inhibited glycol.

Use distilled, deionized, or condensate water, because water from some sources contains elements that reduce the effectiveness of the inhibited formulation. If water of this quality is unavailable, water containing less than 25 ppm chloride, less than 25 ppm sulfate, and less than 100 ppm of total hardness may be used.

Fluid maintenance. Glycol concentrations can be determined by refractive index, gas chromatography, or Karl Fischer analysis for water (assuming that the concentration of other fluid components, such as inhibitor, is known). Using specific gravity to determine glycol concentration is unsatisfactory because: (1) specific gravity measurements are temperature sensitive, (2) inhibitor concentrations can change specific gravity, (3) values for propylene glycol are close to those of water, and (4) propylene glycol values are maximum at 70 to 75% concentration.

A rigorous inhibitor monitoring and maintenance schedule is essential to maintain a glycol solution in relatively noncorrosive condition for a long period. However, a specific schedule is not always easy to establish, because inhibitor depletion rate depends on the particular conditions of use. Analysis of samples immediately after installation, after two to three months, and after six months should establish the pattern for the schedule. Visually inspecting the solution and filter residue can detect active corrosion.

Properly inhibited and maintained glycol solutions provide better corrosion protection over brine solutions in most systems. A long, though not indefinite, service life can be expected. Avoid indiscriminate mixing of inhibited formulations. Exercise caution in replacing brine systems with inhibited glycols because brine components are incompatible with glycol formulations.

HALOCARBONS

Many common refrigerants are used as secondary coolants as well as primary refrigerating media. Their favorable properties as heat transfer fluids include low freezing points, low viscosities, nonflammability, and good stability. Chapters 16 and 17 present physical and thermodynamic properties for common refrigerants. Table 14 lists four halocarbon compounds that are commonly used as secondary coolants. Table 15 gives vapor pressure, viscosity, density, specific heat, and thermal conductivity values for methylene chloride. Table 16 gives the same properties for trichlorethylene.

Volatility of R-12 and R-11 must be considered in equipment design. A pressure-tight system is essential when R-12 is used, and it is highly advisable to use R-11 in a closed system to avoid excessive material losses.

Chapter 16, Table 11, summarizes comparative safety characteristics for halocarbons. Threshold Limit Values and Biological Exposure Indices (ACGIH 1988) have more information on halocarbon toxicity.

Table 14 Freezing and Boiling Points of Halocarbon Coolants

Refrigerant	Name	Freezing Point, °F	Boiling Point, °F
12	Dichlorodifluoromethane	−252	−21.6
11	Trichloromonofluoromethane	−168	74.8
30	Methylene chloride	−142	103.6
1120	Trichloroethylene	−123	189

Table 15 Properties of Liquid Methylene Chloride

Temperature, °F	Vapor Pressure, psia	Specific Heat, Btu/lb · °F	Thermal Conductivity, Btu/h · ft · °F	Density, lb/ft³	Viscosity, Centipoise
140	25.4	0.296	0.074	78.3	0.32
122	19.9	0.293	0.076	79.4	0.34
104	14.5	0.289	0.079	80.5	0.37
86	10.2	0.286	0.081	81.6	0.40
68	6.82	0.284	0.083	82.7	0.44
50	4.39	0.282	0.085	83.8	0.48
32	2.73	0.280	0.087	84.9	0.53
14	1.64	0.278	0.089	86.0	0.59
−4	0.97	0.277	0.091	87.1	0.66
